Executive summary

The United Kingdom's (UK) air quality regulations require that the UK undertakes air quality assessments on an annual basis under the Air Quality Standards Regulations 2010 (AQSR) (*legislation.gov.uk*, 2010).

The UK annual air quality assessment for the year 2021 has been undertaken in accordance with the requirements of the AQSR. The assessment takes the form of comparisons of measured and modelled air pollutant concentrations with the limit values, critical levels, target values and long-term objectives set out in the regulations. The AQSR includes a requirement to deduct the contribution to ambient PM from natural sources. The results were published and made available to the public in September 2022 in the form of e-Reporting Data flows (specifically Data flow G on attainment) (*UK-Air*, 2022).

The AQSR sets limit values for the ambient concentrations to be achieved for:

- sulphur dioxide (SO₂)
- nitrogen dioxide (NO₂)
- particles (PM₁₀)
- lead (Pb)
- benzene (C₆H₆)
- carbon monoxide (CO)

The AQSR also includes:

- critical levels for the protection of vegetation to be achieved for ambient concentrations of sulphur dioxide (SO₂) and oxides of nitrogen (NO_x)
- a target value, a limit value, an exposure concentration obligation and exposure reduction targets for fine particles (PM_{2.5})
- target values and long-term objectives for ozone (O₃)

AQSR sets target values for the ambient concentrations to be achieved for:

- Arsenic (As)
- Cadmium (Cd)
- Nickel (Ni)
- Benzo(a)Pyrene (B(a)P)

The UK has been divided into 43 zones for air quality assessment. There are 28 agglomeration zones (large urban areas) and 15 non-agglomeration zones. The status of the zones in relation to the limit values, critical levels, target values and long-term objectives has been assessed.

This report provides a summary of key attainment results from the e-Reporting publication for the AQSR pollutants and technical information on the modelling methods that have been used.

The results of the assessment against limit values are summarised in Table E1. This shows that 10 zones have not achieved full compliance with the annual NO₂ limit value in 2021.

Table E2 summarises the results of the assessment for O₃ in terms of the numbers of zones with exceedances of the target values and long-term objectives. Ozone concentrations typically show considerable variation from year to year as a result of variation in weather conditions.

Table E3 shows that there were no exceedances of the target value, limit value or exposure concentration obligation for PM_{2.5}.

The results of the assessment against the target values for As, Cd, Ni and B[a]P are presented in Table E4. Four zones have not achieved full compliance with the annual Ni target value and two zones have not achieved full compliance with the annual B(a)P target value in 2021.

Table E1. Summary results of air quality assessment for 2021: comparison with limit values and critical levels

Pollutant	Averaging time	Number of zones exceeding limit value
SO ₂	1-hour	None
SO ₂	24-hour	None
SO ₂	Annual ¹	None
SO ₂	Winter ¹	None
NO ₂	1-hour ²	None
NO ₂	Annual	10 zones (3 measured + 7 supplementary assessment)
NO _x	Annual ¹	None
PM ₁₀	24-hour	None
PM ₁₀	Annual	None
Lead	Annual	None
Benzene	Annual	None
CO	8-hour	None

1 - Critical levels rather than LVs applying to vegetation and ecosystem areas only.

2 - No modelling for 1-hour LV

Table E2. Summary results of air quality assessment for 2021 for O₃: comparison with target values and long-term objectives

Pollutant	Averaging time	Number of zones exceeding target value	Number of zones exceeding long term objective
O ₃	8-hour	none	39 zones (23 measured + 16 supplementary assessment)
O ₃	AOT40	none	1 zone (1 measured)

Table E3. Summary results of air quality assessment for 2021 for PM_{2.5}: comparison with target value and limit value and exposure concentration obligation

Pollutant	Averaging time	Number of zones exceeding target value
PM _{2.5}	Annual target value (25 µg m ⁻³)	None
PM _{2.5}	Annual limit value (20 µg m ⁻³)	None
PM _{2.5}	Exposure concentration obligation (20 µg m ⁻³)	Not exceeded

Table E4. Summary results of AQSR air quality assessment for 2021: comparison with target values

Pollutant	Averaging time	Number of zones exceeding target value
As	Annual	None
Cd	Annual	None
Ni	Annual	4 zones (3 supplementary assessment: Sheffield, South Wales, Yorkshire & Humberside, 1 measured: Swansea)
B(a)P	Annual	2 zones (2 supplementary assessment: Swansea, South Wales)

1 Introduction

1.1 The UK air quality regulations and the EU ambient air quality directives

The United Kingdom's (UK) air quality regulations require that the UK undertakes air quality assessments on an annual basis under the Air Quality Standards Regulations 2010 (AQSR) (*legislation.gov.uk*, 2010).

Prior to 2020 the UK's air quality assessment was undertaken under the European Union directives. The European Union directives on ambient air quality were established to assist member states to achieve protection and improvement of the environment. These directives require member states, which previous to 2020 included the UK, to undertake air quality assessments, and to report the findings of these assessments to the European Commission on an annual basis. Historically this was done according to:

- The Air Quality Framework Directive (1996/62/EC)
- The four Daughter Directives 1999/30/EC, 2000/69/EC, 2002/3/EC and 2004/107/EC.

In June 2008, a new directive came into force: The Council Directive on ambient air quality and cleaner air for Europe (2008/50/EC), which is known as the 'Air Quality Directive' (AQD). This directive consolidated the first three Daughter Directives, and was transposed into AQSR Regulations in England, Scotland, Wales and Northern Ireland in June 2010. The 4th Daughter Directive (AQDD4), 2004/107/EC was also transposed into the AQSR 2010.

The UK annual air quality assessment for the year 2021 has been undertaken in accordance with the requirements of the AQSR. The assessment takes the form of comparisons of measured and modelled air pollutant concentrations with the limit values, critical levels, target values and long-term objectives set out in the regulations. The AQSR includes a requirement to deduct the contribution to ambient PM from natural sources. The results were published and made available to the public in September 2022 in the form of e-Reporting Data flows, specifically Data flow G on attainment) (*UK-Air*, 2022). The 2021 UK submission on air quality is summarised by the annual Air Pollution in the UK reports (Air Pollution in the UK 2021, 2022), which comprise a compliance assessment summary report and a full report, which, in addition, presents air quality modelling data and measurements from the UK national air quality monitoring networks.

The air quality assessment has been reported via the following e-Reporting Data:

- B: Zones and agglomerations
- C: Assessment regime
- D: Assessment methods
- E: Primary validated assessment data
- G: Attainment

Information on the supplementary assessment methods (modelling, diffusion tubes and objective estimations) has been provided in Data flows C and D and results have been provided in Data flows E and G.

The AQSR sets limit values (LVs) for the ambient concentrations to be achieved for:

- sulphur dioxide (SO₂)
- nitrogen dioxide (NO₂)
- particles (PM₁₀)
- lead (Pb)
- benzene (C₆H₆)
- carbon monoxide (CO)

The AQSR also includes:

- critical levels (CL) for the protection of vegetation to be achieved for ambient concentrations of sulphur dioxide (SO₂) and oxides of nitrogen (NO_x)
- a target value (TV), a limit value, an exposure concentration obligation (ECO) and national exposure reduction targets (NERT) for fine particles (PM_{2.5})

- target values (TVs) and long-term objectives (LTOs) for ozone (O₃)

The AQSR sets target values to be achieved for:

- arsenic (As)
- cadmium (Cd)
- nickel (Ni)
- polycyclic aromatic hydrocarbons with benzo(a)pyrene (B(a)P) as an indicator species

The number of monitoring sites required for compliance defined within the AQSR is reduced if other means of assessment, in addition to fixed monitoring sites, are available for inclusion in the annual air quality assessment. Air quality modelling has been carried out to supplement the information available from the UK national air quality monitoring networks. Diffusion tube data from the recently established UK Urban NO₂ Network (UUNN) was included as part of the supplementary assessment for 2021 after being included in 2020 for the first time. The diffusion tube data can be found on UK-Air (*UK-Air*, 2022), there is also a report for 2021 (Environment Agency/Joint Air Quality Unit, 2022).

1.2 This report

This report comprises technical information on the modelling methods that have been used for the assessed year, a summary of key attainment results from the e-Reporting submission for the AQSR pollutants, and key comparisons of findings for measured and modelled air pollutant concentrations with the limit values, critical levels, target values and long-term objectives set out in the regulations. The results of the air quality assessment for 2021 are summarised in Section 2. Section 3 introduces the method that was used to account for the changes in emissions caused by the coronavirus pandemic in 2021.

Sections 4 to 12 of this report describe the Pollution Climate Mapping (PCM) modelling methods that have been used to calculate concentrations of SO₂, NO_x, NO₂, PM₁₀, PM_{2.5}, C₆H₆, O₃, heavy metals (Pb, As, Cd, Ni) and B(a)P for 2021 as part of the assessment of compliance with the limit values, critical levels, target values and long term objectives for each pollutant. This includes:

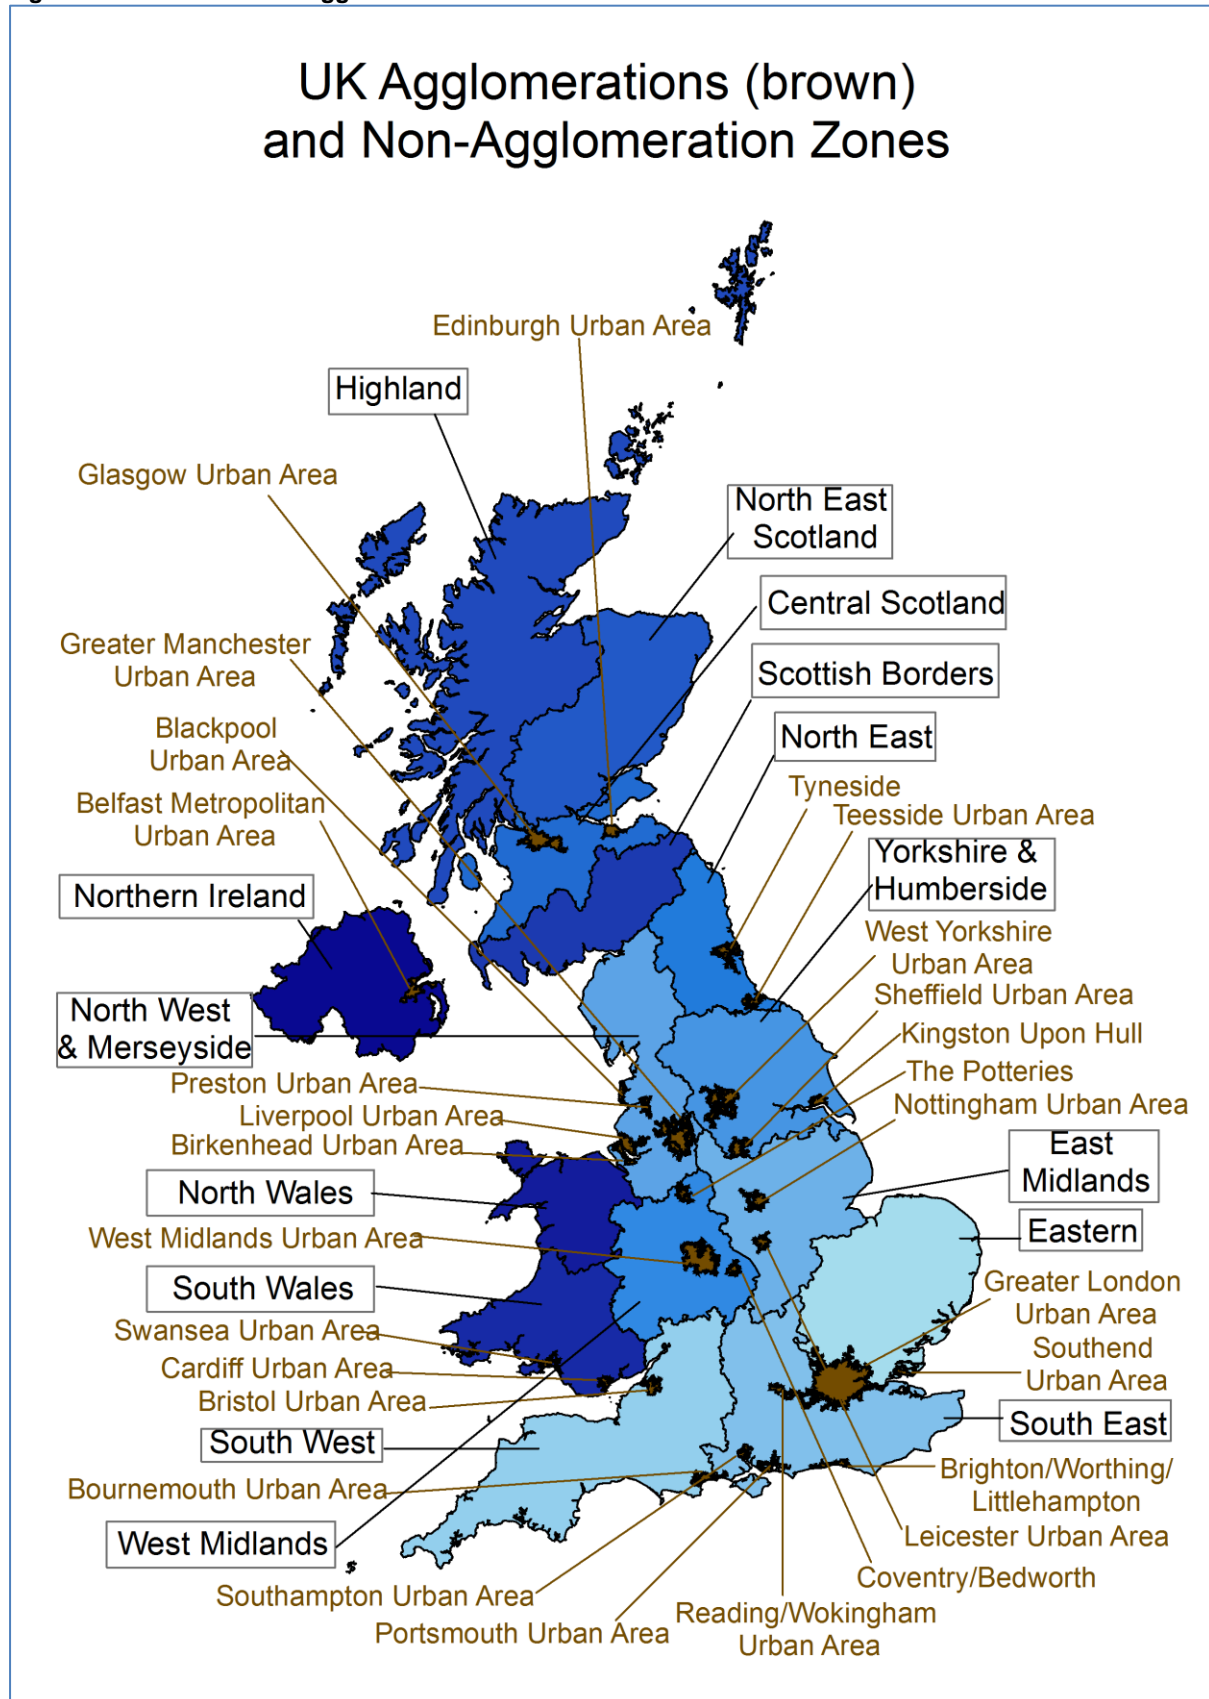

- A summary of the limit values, critical levels, target values and long-term objectives set out in the regulations for each pollutant
- Details of the modelling methods including summaries of inputs, assumptions and schematic flow diagrams of the modelling process
- Source apportionment information
- Information on the verification of the models used and comparisons with data quality objectives

The assessment for CO is described in Section 9. Prior to 2011 a modelling assessment was completed for CO. However, as ambient concentrations throughout the UK have been well below the limit value and assessment thresholds for many years, models are no longer required for CO and the supplementary assessment for 2021 has been based on objective estimation, as it was for 2011-2020.

1.3 Assessment regime and definition of zones

The regulations include a requirement to undertake preliminary assessments of ambient air quality. The objectives of these assessments were to establish estimates for the overall distribution and levels of pollutants, and to identify additional monitoring. The preliminary assessment (Bush, 2000) carried out for 1st Daughter Directive (AQDD1), 1999/30/EC, defined a set of zones to be used for air quality assessment in the UK. The preliminary assessment for the UK for AQDD4 was reported by (Bush, 2007). The AQD includes a similar requirement for continued assessment under Article 4, the preliminary assessment for the UK fulfilling this requirement was reported by (Vincent, Bush and Telling, 2010). The AQSR continues the requirement for the establishment of zones and agglomerations. Table 1.1 contains details of area, population and urban road length contained in each UK zone and agglomeration. The population data are mid-year estimates for 2020 derived from data provided by the Office for National Statistics for England and Wales, National Records of Scotland and Northern Ireland Statistics and Research Agency. Output area totals have been assigned to 1 km grid squares using residential information from OS address base. The zones and agglomerations map for the UK is presented in Figure 1.1.

Figure 1.1 - UK zones and agglomerations for 2021

* ag = agglomeration zone; non-ag = non-agglomeration zone

The status of zones in relation to the limit values, target values, critical levels and long-term objectives for the AQSR pollutants have been reported to via e-Reporting (*UK-Air*, 2022) and a summary of the results of the assessments are included in Section 2. The status has been determined from a combination of fixed monitoring data from the Automatic Urban and Rural Network (AURN), Heavy Metals Network and Polycyclic Aromatic Hydrocarbons Network; indicative monitoring data from the UK Urban NO₂ Network (UUNN); and model results. A comparison of the results of similar assessments carried out since 2001 (Stedman, Bush and Vincent, 2002; Stedman *et al.*, 2003, 2005, 2006; Bush, Targa and Stedman, 2006; Bush *et al.*, 2007; Kent and Stedman, 2007, 2008; Kent, Grice, Stedman, Bush, *et al.*, 2007; Kent, Grice, Stedman, Cooke, *et al.*, 2007; Grice *et al.*, 2009; Yap *et al.*, 2009; Grice, Brookes, *et al.*, 2010; Grice, Cooke, *et al.*, 2010; Kent, Stedman and Yap, 2010; Walker *et al.*, 2010, 2011; Brookes *et al.*, 2011, 2012, 2013, 2015, 2016, 2017, 2019b, 2019a, 2020, 2021; Pugsley *et al.*, 2022) has been reported in Air Pollution in the UK 2021 (Air Pollution in the UK 2021, 2022).

1.4 Monitoring sites

The fixed monitoring stations operating during 2021 for AQSR reporting have been listed within e-Reporting Data flow C (Assessment Regimes), which can be found on UK-AIR (*UK-Air*, 2022). Not all sites had sufficient data capture during 2021 for data to be reported. The data quality objective (DQO) for AQSR measurements is 90% data capture. The Implementing Provisions on Reporting (IPR) guidance (IPR 2013) states that when checking for compliance the minimum data quality objective can be reduced to take into account the proportion of time taken in a calendar year for planned maintenance and calibration. The IPR states that an estimation of this time is 5%, which makes the data quality objective 85%. For the purposes of compliance reporting all measurements from monitoring sites with at least 85% data capture for the entire year have been included. These have been supplemented with monitoring sites with data capture of 75%-84%. These results have been classified in the assessment as 'indicative', rather than fixed in this instance, for the zones they represent. Monitoring stations with at least 75% data capture have been included in the modelling analysis to ensure that a greater number of operational monitoring sites have been used for model calibration and verification purposes.

Measurements from the UK Urban NO₂ Network with at least 85% data capture have also been included in the compliance assessment as part of the supplementary assessment. These measurements have not been used in model calibration.

The monitoring data for the sites used in the assessment for heavy metals and B(a)P are summarised in Appendix 2 - Monitoring sites for As, Cd, Ni, Pb and B(a)P.

1.5 Data quality objectives for modelling results and model verification

The AQSR sets data quality objectives (DQOs) for modelling uncertainty, within supplementary assessment under the AQSR. Uncertainty is defined in the AQSR as the maximum deviation of the measured and calculated concentration levels for 90% of individual monitoring points over the period considered by the limit value (or target value), without taking into account the timing of events. The uncertainty of modelling should be interpreted as applicable in the region of the appropriate LV or TV. The fixed measurements that have been selected for comparison with the modelling results should be representative of the scale covered by the model. Final guidance clarifying the recommended methods for assessing model performance with respect to the DQOs has yet to be agreed. The comparisons with monitoring data presented in this report have therefore included data from all sites including those with measured values not in the vicinity of the LVs or TVs and a highly detailed assessment of the spatial representativity of the sites has not been carried out.

Under the AQSR, DQOs have been set at 50% for hourly averages, daily averages and 8-hour averages of SO₂, NO₂, NO_x, CO and O₃. DQOs have been set at 30% for annual averages of SO₂, NO₂ and NO_x. For PM₁₀, PM_{2.5} and Pb the DQO for annual averages is 50%. DQOs have not been defined for daily averages of PM₁₀. DQOs have been set at 60% for annual averages of As, Cd, Ni and B(a)P.

The models used to calculate the maps of NO_x, NO₂, PM₁₀, PM_{2.5}, C₆H₆, O₃, and B(a)P presented in this report have been calibrated using data from the national monitoring network sites. Data from these sites alone does not allow an independent assessment of the validity of the mapped estimates

in relation to the DQOs for modelling. Measurement data from sites not included in the calibration are described as 'verification sites' in this report and are used in addition to the national monitoring network sites to make this assessment, except for C₆H₆ and B(a)P where no independent data are available. Data from sites quality assured by Ricardo under contract and not part of the national network, including Local Authority sites with data available from the Air Quality England website, Scottish Air Quality Archive monitoring sites, Welsh Air Quality Network monitoring sites, Northern Ireland Automatic Urban Network sites, and Heathrow Airwatch sites, have therefore been used for the verification of the modelled estimates. The description 'Verification Sites' is used to describe the independent monitoring sites included in the verification analysis. Monitoring data has also been obtained for the London Air Quality Network (LAQN) and other local authority monitoring networks for which data are provided by Imperial College London (ERG). The 'Verification Sites' used for the 2021 assessment are listed in Appendix 1 - Monitoring sites used to verify the mapped estimates.

The model used to calculate maps of SO₂ presented in this report is not calibrated because modelled values provide a reasonably good fit to measured concentrations and to avoid the risk of overfitting for the high percentile metrics. Modelled results have therefore been compared to and verified using a combination of national network monitoring data along with the 'Verification Sites' listed in Appendix 1 - Monitoring sites used to verify the mapped estimates. The models used to calculate maps of air pollution from heavy metals (Pb, As, Cd, Ni) presented in this report are also not calibrated. Results have been compared to and verified using national network monitoring data for those sites that are listed in Appendix 2 - Monitoring sites for As, Cd, Ni, Pb and B(a)P in order to ensure that the model assumptions and parameter values selected provide good agreement with measurements. Sites with data capture of at least 75% have been included in the verification analysis. Model verification results are listed in the sections on each pollutant.

1.6 Air quality modelling

Full details of the modelling methods implemented are given in Sections 4 to 12 including summaries of inputs, assumptions and schematic flow diagrams of the modelling process. A brief introduction is presented here.

1.6.1 Background concentration maps

Maps showing background concentrations for NO_x, SO₂ and C₆H₆ have been calculated at a 1 km x 1 km resolution for the relevant metrics set out in the AQSR. These maps have been calculated by summing contributions from the following sources:

- Large point sources¹ – modelled using the air dispersion model ADMS and emissions estimates from the UK National Atmospheric Emissions Inventory 2020 (NAEI 2020).
- Small point sources – modelled using the small points model and emissions estimates from the NAEI 2020.
- Emissions Trading Scheme² (ETS) point sources – those above the large point source modelling threshold or with emission release characteristics are modelled as large point sources, those below the modelling threshold are modelled using the small points model and emissions estimates from the NAEI 2020.
- Distant sources – characterised by the rural background concentration.
- Area sources³ related to domestic combustion – modelled using a time varying dispersion kernel and emissions estimates from the NAEI 2020.
- Area sources related to combustion in industry – modelled using the small points model and emissions estimates from the NAEI 2020.
- Area sources related to road traffic – modelled using a dispersion kernel using time varying emissions and emissions estimates from the NAEI 2020.
- Other area sources – modelled using a dispersion kernel and annual emissions estimates from the NAEI 2020.
- Fugitive point source emissions – modelled using fugitive source kernel model and an estimate of the fugitive component of emissions derived from the NAEI 2020 (C₆H₆ only).

1 km x 1 km background concentration maps for B(a)P have been calculated using a similar approach except that a regional background has not been included and area sources related to industrial

¹ Point source emissions are defined as emissions of a known amount from a known location (e.g. a power station).

² Emissions Trading Scheme point emissions estimates for Air Quality pollutants based on reported carbon emissions

³ Area source emissions are defined as 'diffuse emissions' from many unspecified locations (e.g. emissions from domestic heating, or from shipping).

combustion and ETS point sources not meeting the large point source modelling criteria have been modelled using an area source dispersion kernel.

For PM₁₀ and PM_{2.5} a similar approach has been used to generate 1 km x 1 km background concentration maps. For these pollutants, the following additional contributions have also been included:

- Secondary inorganic aerosol – derived by interpolation and scaling of measurements of SO₄, NO₃ and NH₄ at rural sites.
- Secondary organic aerosol – semi-volatile organic compounds formed by the oxidation of non-methane volatile organic compounds. Estimates derived from results from the NAME model.
- Regional primary particles – from results from the TRACK model and emissions estimates from the NAEI 2020 and EMEP.
- Regional calcium rich dusts from re-suspension of soils – modelled using a dispersion kernel and information on land use.
- Regional iron rich dusts from re-suspension – assumed to be a constant value, estimated measurements made in the vicinity of Birmingham.
- Iron rich dusts from re-suspension due to vehicle activity – modelled using a dispersion kernel and vehicle activity data for heavy duty vehicles.
- Sea salt – derived by interpolation and scaling of measurements of chloride at rural sites.
- Residual – assumed to be a constant value.

A similar approach has also been used for Pb, As, Cd and Ni to generate 1 km x 1 km background concentration maps. For these pollutants, the following additional contributions have also been included:

- Regional concentrations – derived from estimates of primary PM from regional sources calculated using the TRACK model and emissions estimates from the NAEI 2020 and EMEP.
- Re-suspension from bare soils – derived from estimates of re-suspension of PM modelled using a dispersion kernel and information on land use.
- Re-suspension as a result of vehicle movements – derived from estimates of re-suspension of PM modelled using a dispersion kernel and vehicle activity data for heavy duty vehicles.

1.6.2 Roadside concentration maps

Maps showing modelled roadside concentrations of NO_x, PM₁₀, PM_{2.5} and C₆H₆ have been calculated for 9148 urban major road census points (A-roads and motorways) across the UK. Some of the lengths of road associated with each census point cross zone boundaries and thus a total of 9689 road links have been included in the analysis. The road lengths have been split between zones for assessment where a road has length in more than one zone. These roadside concentrations have been calculated by adding a 'roadside increment' concentration component (derived from the road link emission) to the modelled background concentration for each road. This roadside increment concentration has been calculated using the PCM Roads Kernel Model (PCM-RKM). The PCM-RKM, based upon dispersion kernels generated by the ADMS-Roads dispersion model, represents a more process-based approach than the previous empirical method (e.g. Brookes et al. 2015). It provides a more robust assessment, whilst retaining the link with measurement data by using AURN measurement data to calibrate this component of the model. Full details of the PCM-RKM are provided in Appendix 8 – The PCM Roads Kernel Model.

The PCM model provides roadside concentrations for major urban roads. The assessment of roadside concentration for 2021 incorporates an updated classification of urban and rural roads in England, Scotland and Wales. This classification uses an updated evidence base – 2011 Census data for built-up areas in England and Wales and similar data for Scotland, and underlying mapping from OS Open Roads – to provide an improved assessment of the road network in urban and rural areas. Details can be found in the NAEI mapping report (Tsagatakis *et al.*, 2022). The revised underlying mapping was first implemented for the 2018 compliance assessment modelling and the updated classification of urban and rural roads was first implemented for the 2019 compliance assessment modelling.

1.6.3 NO₂ maps

Background and roadside NO₂ concentration maps have been calculated by applying a calibrated version of the updated oxidant-partitioning model. This model describes the complex inter-relationships between NO, NO₂ and O₃ as a set of chemically coupled species (Jenkin, 2004, 2012; Murrells *et al.*, 2008).

1.6.4 Key input data

Emissions inventory data used in this modelling is taken from the NAEI 2020 (Churchill *et al.*, 2022). Emission estimates for area and point sources (taking into account plant closure) have been scaled forward from 2020 to 2021. Additionally a scaling factor to account for the changes in activity and therefore emissions has also been used, see Section 3 for further details. Work carried out to calculate emissions from aircraft and shipping within the PCM model is described in Appendix 6 – Method for calculating and mapping emissions from aircraft and shipping. Dispersion modelling has been done using ADMS 5.2 using meteorological data from the Weather Research and Forecasting (WRF) Model see Appendix 4 – WRF meteorology. UK national network monitoring data has been used to calibrate the background and roadside models, as discussed above in Section 1.5. Further details on inputs and assumptions are provided in Sections 3 to 12.

1.6.5 Ozone maps

Maps of the O₃ metrics specified in the AQSR have been calculated using a different modelling approach to the approach used for other pollutants in this report. This is because of the complex chemistry involved in the production and destruction of O₃. An empirical method based on a combination of interpolation of O₃ measurements at rural sites and model results for NO_x is used to model O₃ concentrations. This is described in Section 10.

1.7 Air quality in Gibraltar in 2021

Air quality monitoring and assessments are also undertaken in Gibraltar and the results of the assessment are published and made available to the public. Further information on air quality monitoring in Gibraltar can be found at <http://www.gibraltarairquality.gi>.

2 Results of the air quality assessment for 2021

The results of the air quality assessments for AQSR pollutants SO₂, NO₂ and NO_x, PM₁₀, PM_{2.5}, Pb, C₆H₆, CO, O₃, As, Cd, Ni and B(a)P have been listed in Table 2.1 to Table 2.6.

These tables summarise information from e-Reporting Data flow G (Attainment) published on UK-Air (UK-Air, 2022) relating to compliance with the respective LV, TV or LTO. The tables have been completed as follows:

- Where all measurements were within the relevant LVs in 2021, the table shows this as “OK”.
- Where compliance was determined by supplementary assessment, this is shown as “OK (s only)”.
- Where locations were identified as exceeding a LV, this is identified with “>LV”. In general, where the status of a location was determined by supplementary assessment, this is indicated by (s only) as done here for compliance.

A similar approach has been used to summarise results in relation to critical levels (CLs), TVs and LTOs. Zones that complied with the relevant CLs, LVs, TVs or LTOs are shaded blue, while those in exceedance are shaded red. For O₃, exceedances of the LTO but not the TV are shaded purple. “n/a” means that an assessment is not relevant for a zone, such as for the vegetation critical level in agglomeration zones.

Measurements are regarded as the primary basis for the compliance status if both measurements and supplementary assessment estimates show that a threshold has been exceeded. Where locations have been identified as exceeding by modelling this indicates that modelled concentrations were higher than measured concentrations or that measurements were not available (or not required for that zone as determined by a 5-yearly assessment of concentrations relative to lower and upper assessment thresholds in the AQSR) and modelled values were therefore used. Modelled concentrations may be higher than measured concentrations because the modelling studies provide estimates of concentrations over the entire zone. It is possible that the locations of the monitoring sites do not correspond to the location of the highest concentration in the zone, for example, there may be no roadside monitoring sites in a zone. Compliance can be determined by modelling where measurements including diffusion tube indicative measurements from the UUNN are not available for a zone. Where AURN and/or UUNN measurements of NO₂ concentrations are available for a specific road link, the measured concentration is used in preference to the modelled concentration for the compliance assessment for that road link. The order of priority is AURN in preference to UUNN in preference to modelling.

CO concentrations were not modelled as part of the compliance assessment due to the sparsity of the monitoring network, low concentrations, and very low risk of limit value exceedance. Therefore in zones where measurements were not available compliance has been determined through objective estimation. These are represented as ‘(s only)’ in the tables below as objective estimation is treated as a modelling approach in e-Reporting. The objective estimation process is explained further in Section 9.

Table 2.2 shows that ten zones have not achieved full compliance with the annual NO₂ limit value in 2021. All zones were compliant with the hourly limit value in 2021. The 1-hour limit value of 200 µg m⁻³ as a 98th percentile was not exceeded in 2021.

Table 2.3 shows that all zones were compliant with both the daily mean limit value and annual mean limit value for PM₁₀ before subtraction of natural sources (required by the AQSR). The exposure concentration obligation for the average of annual mean PM_{2.5} concentrations measured in urban areas of 20 µg m⁻³ was also met (see Section 7.6). Compliance with the PM_{2.5} Limit Value and National Exposure Reduction Target (NERT) was also achieved in 2021.

Table 2.4 shows that all zones were compliant with the limit values for lead, CO and benzene.

Table 2.5 shows that the TV for health was met and the LTO for health for O₃ was exceeded in 39 zones. The TV for vegetation was met in all zones and the LTO for vegetation for O₃ was exceeded in 1 zone in 2021.

Table 2.6 shows that two zones have not achieved full compliance with the annual B(a)P target value and four zones have not achieved full compliance with the annual Ni target value in 2021.

3 Covid-19 pandemic impacts

3.1 Introduction

2020 was an exceptional year for air quality because of the substantial changes (mostly reductions) in emissions activity caused by the national and regional lockdowns that were introduced as a result of the Covid-19 pandemic. Activity levels during 2021 were higher than in 2020 but not fully back to pre-2020 levels, particularly during the early part of the year due to continuing lockdowns. Emissions estimates from the 2020 NAEI have been used to estimate emissions for 2021 for the modelling for the 2021 compliance assessment but additional steps have been taken to capture the impact of the exceptional changes in activity. Levels of activity do not typically vary by a large amount from year to year and in previous years emissions used in the compliance assessment modelling have been calculated by scaling forward emission estimates by one year based on emission projections from the NAEI. Such an approach was not suitable for 2020 or 2021. The exceptional changes in activity levels during 2020 and 2021 have therefore been accounted for in the compliance assessment modelling as follows:

- Emissions for NO_x, PM₁₀ and PM_{2.5} from road transport for 2021 were calculated using road link specific traffic counts for 2021 published by DfT. Road traffic emissions for 2021 for other pollutants, for which the road transport contribution is much smaller, were calculated from 2020 values from the 2020 NAEI using an activity scaling factor derived from quarterly traffic statistics published by DfT.
- 2021 emissions for non-road traffic sources were calculated from 2020 values from the 2020 NAEI using pollutant specific scaling factors at a SNAP code level. The scaling factors for most sources were derived from a combination of published ONS Index of Production (ONS, 2021) and BEIS Energy Trends statistics for 2020 and 2021 (BEIS, 2020). Factors for aircraft were derived from CAA summary monthly statistics (CAA, 2020). Factors for rail were derived from train km data published by ORR (ORR, 2021b, 2021a). Factors for shipping were derived from DfT quarterly port statistics (DfT, 2022b).

For most pollutants the models are calibrated using measurements from the national networks to ensure that they are grounded in reality – uncertainty in the emissions and model results was inevitably higher for 2020 and 2021 than in previous years but the calibration using high quality measurements improves confidence in the results.

For 2020, emissions estimates calculated from the pre-pandemic 2019 NAEI were typically scaled down. For 2021, emissions estimates calculated from the strongly pandemic influenced 2020 NAEI were typically scaled up, but in some instances not fully back to pre-pandemic levels.

Further details on the methods used to estimate emissions for 2021 are provided in this section.

3.2 Road Transport

3.2.1 Introduction

The NAEI calculates link by link emissions for A-roads and motorways (major roads) for NO_x, PM₁₀ and PM_{2.5} and benzene for approximately 18,000 road links in the UK, of which about 9000 are the urban road links that are included in the PCM roadside modelling for the compliance assessment modelling. These link-by-link emissions are based on traffic counts for each specific road link and are summed to provide values for 1 km grid squares. The gridded major road emissions are combined with grids for minor roads and cold starts (and brake and tyre wear and road abrasion for PM) to calculate total gridded road transport emissions for inclusion in the PCM modelling for background locations. Full details of the emissions mapping method for road transport are provided in the NAEI mapping report (Tsagatakis *et al.*, 2022).

The emission mapping for road transport for other pollutants is based on fuel consumption and is not mapped at the same level of detail.

In compliance assessments prior to 2020, emissions estimates were provided by the NAEI for the year prior to the assessment year and are based on the traffic counts for individual major road links for that prior year. In previous years the link by link and gridded emissions were then scaled forward one year by the application of scaling factors based on NAEI emissions projections. Road link NO_x emissions were previously calculated on a link-by-link basis based on activity and emission factor scaling, because road transport is such a dominant source for NO_x and NO₂. Link by link PM₁₀, PM_{2.5} and benzene emissions and gridded emissions were previously scaled forward based on a comparison of national totals.

A revised method was adopted for the 2020 and 2021 compliance assessment modelling in order to account for the large changes in activity between 2019, 2020 and 2021.

3.2.2 NO_x, PM₁₀ and PM_{2.5}

The methods used to calculate link by link and gridded emissions maps for NO_x, PM₁₀ and PM_{2.5} for 2021 are described in this section.

DfT provided 2021 traffic counts (Annual Average Daily Flow) (DfT, 2022a) for inclusion in the 2021 compliance assessment modelling and these counts were used along with 2021 specific fleet weighted emission factors to calculate link by link emissions for 2021.

Link by link emissions have been calculated for a total of 18,436 road links for 2021. 2021 traffic counts were available for 17,777 of these roads. Generic scaling factors were used for the remaining roads where 2021 counts were not available as follows:

- The DfT road geography and count point assignment are year specific. The count point allocations change from year to year where there are changes to the road network or where DfT revise the locations at which counts are made. For 318 roads in GB outside London the DfT road geography and count point assignment did not provide a direct match between the 2020 and 2021 datasets;
- 12 roads in London for which the DfT road geography and count assignment did not provide a direct match between the 2020 and 2021 datasets;
- 329 road links in Northern Ireland.

Generic 2020 to 2021 scaling factors for each vehicle type were derived from DfT quarterly traffic statistics (vehicle km) (DfT, 2021a) for 2020 and 2021 and were applied to roads outside London, including in Northern Ireland. London specific 2020 to 2021 scaling factors were derived from a comparison of the DfT counts for roads in London in 2020 and 2021 for which counts were available for both years.

The NAEI includes estimates for taxi emissions for roads in London. The split between car and taxi counts for each road is based on data provided by TfL for a non-pandemic year.

Minor road emissions maps for 2021 were also calculated based on 2021 traffic counts and vehicle km data.

3.2.3 Other pollutants

A single 2021/2020 scaling factor was applied for the road transport emissions of other pollutants, for which the road transport contribution is much smaller. This scaling factor was derived from a comparison of vehicle km data for all traffic from DfT quarterly traffic statistics for 2020 and 2021. The value is shown in Table 3.2 below.

3.2.4 Temporal profiles

A 2021 specific monthly profile for road transport emissions was used for 2021 to account for the impact of Covid-19 lockdowns. This profile was derived from daily traffic statistics published by DfT

(DfT, 2021b) and is shown in Figure 3.1. The hourly and daily emission profiles were unchanged from those used previously and are included in Appendix 5 – Dispersion kernels for the area source model.

Figure 3.1 - Normalised monthly profile of road transport emissions for 2021

3.3 Other area sources

The starting point for the 2021 PCM compliance assessment modelling was the 1 km gridded maps emissions for 2020 from the 2020 NAEI. The normal method for scaling the area source emissions estimates to 2021 would be to use source activity specific scaling factors for area sources with the factors derived from the NAEI emissions projections.

For 2020 and 2021 we have prepared a specific set of Covid-19 2020/2019 and 2021/2020 factors for non-road transport area sources at the SNAP code sector level and have applied these directly to the 2020 NAEI 1 km emissions maps. We have calculated scaling factors on an annual basis based on the monthly, quarterly or annual statistics that are available for each source.

Table 3.1 shows the data sources for each sector. For many sectors we have derived pollutant specific scaling factors. The activity scaling is the same for specific sources and activities but the fuel mix contributing to national totals varies by pollutant and thus the scaling factors aggregated to the SNAP sector level vary.

Table 3.1 - The data sources for 2021/2020 non-road transport Covid-19 scaling factors for 2021

Snap	Source	Data source
1	Energy Production	A combination of ONS Index of Production (Monthly)(ONS, 2021) ONS Index of Services (Monthly) (ONS, 2020b), BEIS Energy Trends (BEIS, 2020) (Quarterly). Energy Trends most influential dataset.
2	Commercial	A combination of ONS Index of Production, ONS Index of Services, BEIS Energy Trends. Energy Trends most influential dataset.
2	Domestic	BEIS Energy Trends.

3	Industry	A combination of ONS Index of Production, ONS Index of Services, BEIS Energy Trends. Index of Production most influential dataset.
4	Processes	A combination of ONS Index of Production, ONS Index of Services, BEIS Energy Trends. Index of Production most influential dataset.
5	Energy Extraction	A combination of ONS Index of Production, ONS Index of Services, BEIS Energy Trends.
6	Solvents	A combination of ONS Index of Production, ONS Index of Services, BEIS Energy Trends. Index of Production most influential dataset.
7	Road Transport	Remapped in detail using DfT 2021 AADF file for NOx, PM10 and PM2.5. Calculated from DfT quarterly traffic statistics for other pollutants scaling.
8	Aircraft	CAA summary monthly statistics (CAA, 2020)
8	Rail	Published data from the ORR data portal for freight (ORR, 2021a) train km and for passenger (ORR, 2021b) train km.
8	Shipping	DfT quarterly port statistics.
8	Off-road Industry	ONS Construction output data (volume by sector in £million) (ONS, 2020a)
8	Off-road (Air support)	Calculated as the average of passenger and aircraft movement data from CAA in order to get best estimate of air support activity changes.
8	Off-road (Agriculture)	Assume no change from normal (use 2020 values).
8	Off-road (House and Garden)	Assume no change from normal (use 2020 values).
8	Snap 8 other (Boats)	Assume no change from normal (use 2020 values).
9	Waste	A combination of ONS Index of Production, BEIS Energy Trends. Index of Production most influential dataset.
10	Agriculture	Assume no change from normal (use 2020 values).
11	Other	Assume no change from normal (use 2020 values).

Table 3.2 shows the factors that have been calculated for each pollutant. For most sectors the factors are above or fairly close to unity. For most sectors this results in levels of activity close to pre-pandemic levels. The exception is for aircraft and air support, where scaling factors close to unity reflect a continuation of much lower activity levels than in earlier years.

In previous assessments we have compared temperature data for the compliance year and the NAEI year in order to calculate a scaling factor to apply to domestic emissions. The BEIS energy trends data used to calculate the 2021/2020 Covid-19 scaling factors should already incorporate the influence of temperature on energy demand and thus an additional scaling was not required for 2021.

Table 3.2 - 2021/2020 Covid-19 scaling factors for 2021 PCM compliance modelling

Snap	Source	NO _x	SO ₂	As	Cd	Ni	Pb	NH ₃	Benzene	PM ₁₀	B[a]p	PM _{2.5}

* Remapped in detail using DfT 2021 AADF file for NO_x, PM₁₀ and PM_{2.5}.

3.4 Point sources

Emissions estimates for point sources are normally projected forward one year using source specific scaling factors derived from the NAEI emissions projections. For 2021 the emissions for point sources were projected forward one year to 2021 from 2020 using the same SNAP sector and pollutant specific scaling factors listed in Table 3.2 that were used for area sources in order to account for the impact of the lockdowns.

3.5 Regional PM

The emissions estimates for the UK sources that contribute to the modelled regional primary PM concentrations were also scaled forward to 2021 from 2020 values using the factors listed in Table 3.2. Emissions estimates for European sources scaled forward to 2021 from 2019 values using the product of 2020/2019 factors and 2021/2020 factors. Regional PM concentrations are a component of the modelling for PM₁₀, PM_{2.5} and for heavy metals.

4 NO₂/NO_x

4.1 Introduction

4.1.1 Limit values

Two limit values for ambient NO₂ concentrations are set out in the Air Quality Standards Regulations (AQSR) (*legislation.gov.uk*, 2010). These have been specified for the protection of human health and came into force from 01/01/2010. These limit values are:

- An annual mean concentration of 40 µg m⁻³.
- An hourly concentration of 200 µg m⁻³, with 18 permitted exceedances each year.

A critical level for NO_x for the protection of vegetation has also been specified in the regulations:

- An annual mean concentration 30 µg m⁻³ (NO_x as NO₂).

Because this critical level is designed to protect vegetation, it only applies in vegetation areas as defined in the regulations.

Results of the assessment in terms of comparisons of the modelled concentrations with the annual mean limit value for NO₂ and critical level for NO_x have been reported in accordance with the AQSR and published on UK-AIR (*UK-Air*, 2022)⁴.

4.1.2 Annual mean modelling

Annual mean concentrations of NO_x and NO₂ have been modelled for the UK for 2021 at background and roadside locations. Figure 4.1 and Figure 4.2 present maps of annual mean NO₂ concentrations for these locations in 2021. These maps have been used for comparison with the annual mean NO₂ limit value described above. To calculate NO₂ annual mean maps, NO_x annual mean concentration maps at background and roadside locations were first calculated.

The modelling methods for annual mean NO_x and NO₂ have been developed over several years (Stedman and Bush, 2000; Stedman, Bush, *et al.*, 2001; Stedman, Goodwin, *et al.*, 2001; Stedman, Bush and Vincent, 2002; Stedman *et al.*, 2003, 2005, 2006; Bush, Targa and Stedman, 2006; Bush *et al.*, 2007; Kent and Stedman, 2007, 2008; Kent, Grice, Stedman, Bush, *et al.*, 2007; Kent, Grice, Stedman, Cooke, *et al.*, 2007; Grice *et al.*, 2009; Yap *et al.*, 2009; Grice, Brookes, *et al.*, 2010; Grice, Cooke, *et al.*, 2010; Kent, Stedman and Yap, 2010; Walker *et al.*, 2010, 2011; Brookes *et al.*, 2011, 2012, 2013, 2015, 2016, 2017, 2019b, 2019a, 2020, 2021; Pugsley *et al.*, 2022).

4.1.3 Overview of the PCM model for NO_x and NO₂

Figure 4.5 shows a simplified flow diagram of the PCM model for NO_x and NO₂. A summary of the PCM model method, input, and assumptions for NO_x and NO₂ is presented in Table 4.1.

Figure 4.5 - Flow diagram for PCM NO_x and NO₂ model

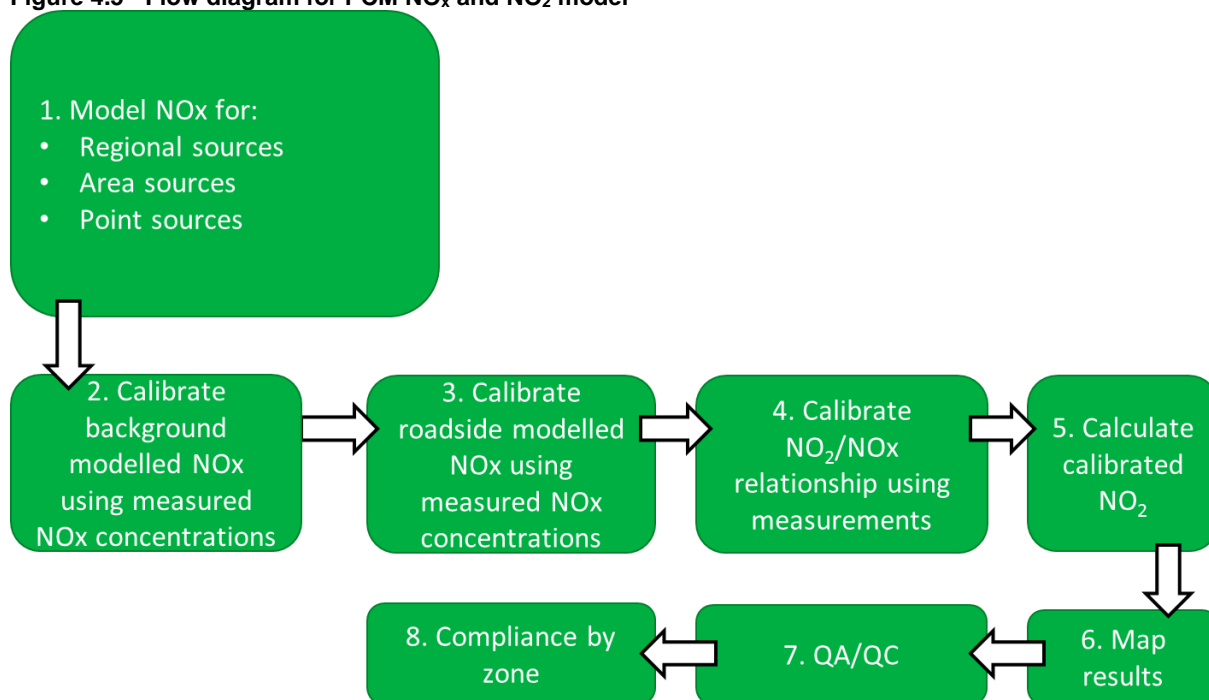

Table 4.1 - PCM model method, input and assumptions summary for NO_x and NO₂

Heading	Component	Details
General	Pollutant	NO _x and NO ₂
	Year	2021
	Locations modelled	Background and traffic locations
	Metric	Annual mean
Input data	Emission inventory	NAEI 2020 (scaled to 2021)
	Energy projections	Energy Projections 2021
	Road traffic counts	2021 (scaled from 2020 where not available)
	Road transport activity projections	DfT (2021) car sales projections, TfL traffic projections for London (2021)
	Road transport emission factors	COPERT 5.4 (COPERT 5.4, 2020)
	Measurement data	2021
	Meteorological data	WRF (see Appendix 4 – WRF meteorology)
	Model components	Regional
	Large point sources	360 sources modelled using ADMS 5.2
	Small point sources	PCM small points model
	ETS point sources	PCM small points model
	Large ETS point sources	54 sources modelled using ADMS 5.2
	Area sources	PCM dispersion kernels generated using ADMS 5.2. Time varying emissions for road transport and domestic sources. PCM small points model for industrial combustion emissions.

Heading	Component	Details
Calibration	Roadside increment	PCM Roads Kernel Model using ADMS-Roads 5.0
	Model calibrated?	Yes
	Number of background stations in calibration	77
	Number of traffic stations in calibration	52
Pollutant specific	Method used to calculate NO ₂ from NO _x	Oxidant partitioning model, calibrated for 2021
	Source of f-NO ₂ assumptions	NAEI January 2022

4.1.4 Outline of the annual mean model for NO_x

The 1 km x 1 km annual mean background NO_x concentration map has been calculated by summing the contributions from:

- Large point sources
- Small point sources
- Distant sources (characterised by the rural background concentration)
- Local area sources
- Point sources with emissions estimates for air quality pollutants based on reported carbon emissions (ETS points)

The area source model has been calibrated using data from the national automatic monitoring networks (AURN) for 2021. At locations close to busy roads an additional roadside contribution has been added to account for contributions to total NO_x from road traffic sources. The contributions from each of these components are described in Section 4.3.

4.1.5 Outline of the annual mean model for NO₂

NO₂ concentrations have been calculated from the modelled NO_x concentrations derived using the approach outlined above using a calibrated version of the updated oxidant-partitioning model described in Section 4.4. This model describes the complex inter-relationships between NO, NO₂ and ozone as a set of chemically coupled species (Jenkin, 2004, 2012; Murrells *et al.*, 2008). This approach provides additional insights into the factors controlling ambient levels of NO₂ (and O₃), and how they may vary with NO_x concentration.

4.1.6 Annual mean NO_x concentration in vegetation areas

The background NO_x map has also been used to generate a map of annual mean NO_x concentrations in vegetation areas for comparison with the NO_x critical level described above; this map is shown in Figure 4.3. This map has been calculated by removing non-vegetation areas from the background NO_x map and calculating the zonal mean of the 1 km x 1 km grid squares for a 30 km x 30 km grid so that it complies with the criteria set out in the AQSR. Mean concentrations on a 30 km x 30 km grid have been used to prevent the influence of any urban area appearing unrealistically large on adjacent vegetation areas. Thus, the modelled concentrations in vegetation areas should be representative of approximately 1000 km² as specified in the AQSR for monitoring sites used to assess concentrations for the vegetation critical level.

4.1.7 Assessment for the 1-hour limit value

Hourly concentrations for comparison with the 1-hour limit value have not been modelled due to the considerable uncertainties involved in modelling at such a fine temporal scale.

The annual mean limit value is expected to be more stringent than the 1-hour limit value in the majority of situations (Air Quality Expert Group (AQEG), 2004). This is illustrated in Figure 4.4 which is a scatter plot of annual mean NO₂ in 2021 against the 99.8th percentile of hourly mean concentration (equivalent to 18 exceedances in the same year). This plot shows that more sites exceed the annual mean limit value of 40 µg m⁻³ than the 200 µg m⁻³ hourly limit value.

4.1.8 Chapter structure

This chapter describes modelling work carried out for 2021 to assess compliance with the NO_x critical level and annual mean NO₂ limit value. Emission estimates for NO_x are described in Section 4.2. Section 4.3 describes the NO_x modelling methods. Details of the methods used to estimate ambient NO₂ from NO_x are presented in Section 4.4. Verification of and source apportionment for the modelling results are presented in Section 4.5.

4.2 NO_x emissions

The NO_x modelling is underpinned by the UK National Atmospheric Emissions Inventory 2020 (NAEI 2020) NO_x emissions estimates (Churchill *et al.*, 2022). Emissions projections have been provided by the NAEI (Personal communication from Ben Pearson, 2022) based on BEIS EEP 2021 energy and emissions projections (BEIS, 2022). The methods used to calculate projections to 2021 from 2020 relating to the ongoing impact of the reduced activity levels in 2020 have been calculated as described in Covid-19 pandemic impacts

Figure 4.6 shows the UK total NO_x emissions for 2021, with the coding described in Table 4.2. The figure shows that NO_x emissions in 2020 are dominated by four main sources:

- SNAP 7: Road transport (exhaust emissions)
- Combustion point sources (SNAP codes 1, 2 and 3)
- SNAP 8: Other Transport & mobile machinery (ships)
- SNAP 3: Combustion in industry

Figure 4.6 - Total UK NO_x emissions for 2021 by SNAP code scaled using Covid factors from NAEI 2020

Table 4.2 - Description of SNAP sector coding

Short code	Description
SNAP 1: Combustion (energy)	SNAP 1: Combustion in energy production & transformation
SNAP 2: Combustion (commercial)	SNAP 2: Combustion in Commercial, Institutional & residential & agriculture (excludes domestic)
SNAP 2: Combustion (domestic)	SNAP 2: Combustion in Commercial, Institutional & residential & agriculture (domestic only)
SNAP 3: Combustion (industry)	SNAP 3: Combustion in industry
SNAP 4: PP (excludes quarrying and construction)	SNAP 4: Production processes (excludes quarrying and construction)
SNAP 4: PP (quarrying)	SNAP 4: Production processes (quarrying)
SNAP 4: PP (construction)	SNAP 4: Production processes (construction)
SNAP 5: Extraction	SNAP 5: Extraction & distribution of fossil fuels
SNAP 6: Solvent use	SNAP 6: Solvent use
SNAP 8: OT&MM (other)	SNAP 8: Other Transport & mobile machinery (other)
SNAP 8: OT&MM (aircraft)	SNAP 8: Other Transport & mobile machinery (aircraft)
SNAP 8: OT&MM (air support)	SNAP 8: Other Transport & mobile machinery (air support)
SNAP 8: OT&MM (industry)	SNAP 8: Other Transport & mobile machinery (industry off road mobile machinery)
SNAP 8: OT&MM (other off road)	SNAP 8: Other Transport & mobile machinery (other off road mobile machinery)
SNAP 8: OT&MM (rail)	SNAP 8: Other Transport & mobile machinery (rail)
SNAP 8: OT&MM (ships)	SNAP 8: Other Transport & mobile machinery (ships)
SNAP 9: Waste	SNAP 9: Waste treatment and disposal
SNAP10: Agriculture	SNAP10: Agriculture forestry & land use change
SNAP 11: Nature	SNAP 11: Nature
SNAP 7: RT (exhaust emissions)	SNAP 7: Road transport (exhaust emissions)
SNAP 7: RT (brake and tyre wear)	SNAP 7: Road transport (brake and tyre wear)
SNAP 7: RT (road abrasion)	SNAP 7: Road transport (road abrasion)
PS: Combustion (SNAP codes 1-3)	Combustion point sources (SNAP codes 1-3)
PS: Other (incl. SNAP codes 4, 5 and 9) *	Other point sources (including SNAP codes 4, 5 and 9)

* PS stands for Point Sources. Emissions that are mapped by the NAEI as area sources are summarised using the split in the rows above, and those that are mapped as point sources are summarised using the split in the last 2 rows of Table 4.2.

4.3 NO_x modelling

4.3.1 NO_x contributions from large point sources

Point sources in the NAEI 2020 have been classified as large if they fulfil either of the following criteria:

- Annual NO_x emissions in the NAEI 2020 are greater than 500 tonnes for any given plant
- Stack parameters are already available for any given plant in the PCM stack parameters database (described in more detail below)

Contributions to ground level annual mean NO_x concentrations from large point sources in the NAEI 2020 were estimated by modelling each source explicitly using the atmospheric dispersion model ADMS 5.2 and sequential meteorological data for 2021 from the Weather Research and Forecasting Model (WRF), as described in Appendix 4 – WRF meteorology. The WRF model is a next-generation

numerical weather prediction modelling system developed by the US National Centre for Atmospheric Science (NCAR) (UCAR, 2020). This method accounts for spatial variation in meteorological parameters across the UK representing local dispersion characteristics within the PCM output. A total of 360 large point sources were modelled. Surface roughness varied at both the dispersion and meteorological sites depending on the area type as presented in Table A5.1. Concentrations were calculated for a 99 km x 99 km square composed of a regularly spaced 1 km x 1 km resolution receptor grid. Each receptor grid was centred on the point source. For each large point source information was retrieved from the PCM stack parameters database. This database has been developed over a period of time under the Modelling of Ambient Air Quality (MAAQ) contract and its predecessors. The database is updated annually as required. Data sources for this database include a survey of Part A authorisation notices held by the Environment Agency and previously collated datasets on emission release parameters from large SO₂ point sources (Abbott and Vincent, 1999). Parameters used in the modelling from the stack parameters database include:

- Stack height
- Stack diameter
- Discharge velocity
- Discharge temperature

Where release parameters were unavailable, engineering assumptions have been applied based on information available for similar plant.

The NAEI emissions for large point sources are for the year 2020; however, the year 2021 has been modelled for the assessment. The emissions estimates for 2021 have been calculated from the 2020 values to take into account the impact of the reduced activity levels in 2020, using the scaling method described in Section 3. Closure of plant or activities are taken into account when deriving the source sector projection factors by subtracting the base year emissions associated with plant closure from the relevant source sector total for point sources for the NAEI base year. Any point sources in the NAEI base year that closed before the start or early in the current assessment year are removed from the modelling, based on recommendations from the NAEI team (Personal communication from Ben Pearson, 2022).

4.3.2 NO_x contributions from small point sources

Contributions from NO_x point sources in the NAEI 2020 that were not classified as large point sources (see Section 4.3.1) were modelled using the small point source model described in Appendix 3 – Small point source model. In line with the method applied for the large point sources the NAEI 2020 emissions for small point sources have been scaled to 2021 using the same source sector specific projection factors applied to the large point sources.

4.3.3 NO_x contributions from ETS point sources

The NAEI 2020 includes point source emissions estimates derived from carbon emissions data reported under the EU-Emissions Trading Scheme (ETS), most recently described in (Tzagatakis *et al.*, 2022). These point sources are referred to as ETS points in this report. These derived air quality pollutant emissions are particularly uncertain and therefore in previous assessments (e.g. (Brookes *et al.*, 2017)) emissions were capped at reporting thresholds and treated as small point sources. For the 2016 assessment (Brookes *et al.*, 2019a) the NAEI recommended treating the ETS points that have emissions greater than the large points modelling threshold as large points and not to apply a cap (Personal communication from Ben Pearson, 2022). The 2021 assessment continues this approach. Thus, based on the criteria for the treatment of large point sources described above (Section 4.3.1), 54 ETS point sources were modelled as an additional set of large point sources (using the approach described in Section 4.3.1). ETS points that were not classified as large point sources were modelled using the small points approach (described in Appendix 3 – Small point source model). In line with the method applied for the large point sources, the NAEI 2020 emissions for ETS point sources have been scaled to 2021 using the same source sector specific projection factors applied to the large point sources, as described in Section 3.

4.3.4 NO_x contribution from rural background concentrations

Rural annual mean background NO_x concentrations have been estimated using:

- NO_x measurements at 10 selected rural AURN sites.
- NO_x estimated from NO₂ measurements at 20 rural NO₂ diffusion tube sites from the UK Eutrophying and Acidifying Atmospheric Pollutants (UKEAP) Network.

Figure 4.7 shows the locations of these monitoring sites and the interpolated rural map.

Rural NO_x was estimated from rural NO₂ at diffusion tube sites by dividing by 0.7835. This factor, which is a typical NO_x/NO₂ ratio measured at rural automatic monitoring sites (Stedman *et al.*, 2003), does not vary significantly between years or across the country. Measurements have then been corrected to remove the contribution from point source and local area sources to avoid double counting these contributions later in the modelling process.

The correction procedure is as follows:

$$\text{Corrected rural background } (\mu\text{g m}^{-3}) = \text{Uncorrected rural background } (\mu\text{g m}^{-3}) - (A + B + C),$$

where: *A* is an estimate of the contribution from area source components, derived using the area source contributions from the 2020 modelling (scaled using the ratio of 2020 and 2021 emissions, covid scaling factors applied to 2021 emissions),

B is the sum of contributions from large point sources based on 2020 modelling,

C is the sum of contributions from small and ETS point sources based on 2020 modelling.

The correction is applied based on 2020 model results for local area and point sources because calibrated model results for these sources for 2021 are calculated later in the modelling process and rely on a calibration that requires the subtraction of the corrected rural contribution. Automatic sites, where available have been used in preference to diffusion tubes as these are considered to be more accurate. An interpolation of corrected rural measurement data by Inverse Distance Weighted (IDW) interpolation has been used to map regional background concentrations throughout the UK.

Figure 4.7 - Rural background NO_x concentrations map with monitoring sites used in the interpolation (annual mean NO_x concentrations for 2021 ($\mu\text{g m}^{-3}$, as NO₂) are shown below the site name)

4.3.5 NO_x contributions from local area sources

In the NAEI 2020, NO_x area source emissions maps have been calculated for each source code-activity code combination using distribution grids that have been generated using appropriate surrogate statistics. These NO_x emissions grids are then added together to give SNAP code sector NO_x area source emission grids. The full method is described in (Tsagatakis *et al.*, 2022). To calculate NO_x area source emission grids for 2021 scaling factors have been used to scale 2020 emissions forwards to 2021 accounting for the impact of the Covid-19 lockdowns, as described in Section 3.3. (BEIS, 2020b). The 2020 area source NO_x emissions have been mapped using updated distribution grids produced for the NAEI 2020 (Tsagatakis *et al.*, 2022).

The 2021 area source emissions maps have then been used to calculate uncalibrated area source concentration maps for each SNAP code sector. With the exception of SNAP sector 3 (combustion in industry), this has been done by applying an ADMS 5.2 derived dispersion kernel to the emission maps to calculate the contribution to ambient concentrations on a 1 km x 1 km receptor grid, from the

area source emissions within a 33 km x 33 km square surrounding each receptor. Hourly sequential meteorological data from the WRF model in 2021 have been used to construct the dispersion kernels. Appendix 5 – Dispersion kernels for the area source model describes these kernels in more detail and explains how they have been calculated.

Since 2011 a dispersion kernel approach including a time varying emission profile based on degree days has been applied to the SNAP 2 domestic area sources sector to weight these emissions more realistically by time of day and meteorological conditions. The approach to derive the time varying emissions profile is described in Appendix 5 – Dispersion kernels for the area source model. In previous assessment we have compared temperature data for the compliance year and the NAEI year in order to calculate a scaling factor to apply to SNAP 2 emissions. Instead for the 2021 assessment the 2021/2020 Covid-19 scaling factor already incorporates the influence of variation in meteorology on energy demand and thus an additional scaling was not required for 2021, as described in Section 3.3.

A development introduced for the 2011 assessment was a revision to the methodology for treating the SNAP 3 (combustion in industry) area source component (i.e. the component of the UK SNAP 3 national total not accounted for by regulated processes). Since 2011 the small points model (described in Appendix 3 – Small point source model) has been applied to derive concentrations resulting from SNAP 3 area source emissions. By using the small points method for this sector, a more realistic release height, buoyancy and momentum of discharge is used based on the magnitude of the emission for small industrial chimneys.

Figure 4.8 shows the calibration of the area source model. The modelled concentrations from all point sources, SNAP 3 area sources and corrected rural NO_x concentrations have been subtracted from the measured annual mean NO_x concentration at background sites. This concentration is compared with the modelled area source contribution (excluding SNAP 3) to annual mean NO_x concentrations to calculate the calibration coefficients used in the area source modelling.

As part of the calibration process, emission caps have been applied to certain sectors; this is because the use of surrogate statistics for mapping area source emissions sometimes results in unrealistically large concentrations in some grid squares for a given sector. The emission caps applied are given in Table 4.3.

The modelled area source contributions for each sector except SNAP 3 were multiplied by the coefficient to calculate the calibrated area source contribution for each grid square in the country. The point source contributions, SNAP 3 area source component and regional rural concentrations were then added, resulting in a map of background annual mean NO_x concentrations.

Figure 4.8 - Calibration of area source NO_x model, 2021 ($\mu\text{g m}^{-3}$, as NO₂)Table 4.3 - Emission caps applied to NO_x sector grids

SNAP code	Description	Cap applied (t/a/km ²)
SNAP 1 (gas production, natural gas)	Combustion in energy production & transformation	30
SNAP 2 (industrial/commercial natural gas combustion)	Combustion in Commercial, Institutional & residential & agriculture	30
SNAP 8 (shipping only)	Other Transport & Mobile Machinery	100

4.3.6 NO_x Roadside concentrations

The modelled annual mean concentration of NO_x at a roadside location is made up of two parts: the background concentration (as described above) and a roadside increment:

$$\text{roadside NO}_x \text{ concentration} = \text{background NO}_x \text{ concentration} + \text{NO}_x \text{ roadside increment.}$$

The NAEI has provided estimates of NO_x emissions for major road links in the UK for 2020 (Churchill *et al.*, 2022) and these have been scaled to provide estimates of emissions in 2021, as described in Section 3.2. The emissions estimates for NO_x from road transport sources include the following assumptions:

- Department for Transport (DfT) 2022 traffic forecasts, (DfT, 2022a) car sales projections including the uptake of low carbon passenger cars and LGVs with electric and hybrid electric propulsion systems, and Transport for London traffic projections for London (2021)
- NO_x emission factors from COPERT 5.4 (COPERT 5.4, 2020)

Prior to the 2020 compliance assessment, traffic speed assumptions by vehicle category were applied following categories based upon UK area type and road type taking data from DfT congestion statistics to estimate the speeds (Brown, Wakeling, Pang, & Murrells, 2018). For the 2020 and 2021 compliance assessment modelling, revised NAEI traffic speed assignments have been applied using

defined urban/rural classification, A-road/motorway and speed limit. Assignments were made separately to roads in central, inner and outer London and the rest of the UK outside of London. Speed limit classification data has been assigned to OS Openroads geometry based on the length weighted median speed limit for each road link. The underlying speed limit dataset has been provided by Basemaps for Great Britain (Speed Limit Data Basemap, 2021). The vehicle speeds assigned to each category were derived from an analysis of GPS vehicle speed observations (Teletrac Navman, 2021) for England provided by DfT. The observed average speeds for England were applied across the UK. Speed limits were manually assigned to road links in Northern Ireland.

Local traffic fleet composition information has been used to calculate road traffic emissions in specific areas for the first time in the 2021 assessment. Information from Automatic Number Plate Recognition has been combined with vehicle registration data in order to derive fleet composition in terms of vehicle ages and Euro standards. Emissions have been 'localised' in the following locations:

- Within the Clean Air Zone in Birmingham
- Within the Clean Air Zone in Bath
- The whole of Leeds City Council

The PCM Roads Kernel Model (PCM-RKM) described in Appendix 8 – The PCM Roads Kernel Model has been used to calculate the roadside increment. The PCM-RKM is based upon dispersion kernels generated by the ADMS-Roads dispersion model (v5.0) and represents a more process-based approach than the previous empirical method. It provides a more robust assessment, whilst retaining the link with measurement data provided using AURN measurement data to calibrate this component of the model.

Figure 4.9 shows the calibration of this model at roadside monitoring sites. In this figure, the measured roadside increment at the roadside monitoring sites is calculated as the measured concentration minus the background NO_x component, which is determined from the background NO_x concentration map described in Section 4.3.5 above. The modelled NO_x roadside increment is calculated directly using the road link emissions alone. The total modelled roadside NO_x concentration is then given from the equation above by adding the calibrated background NO_x modelled concentration to the calibrated NO_x roadside increment modelled concentration. The average distance from the kerb for the roadside and kerbside monitoring sites used to calibrate the roadside increment model is approximately 4 m. The calculated roadside concentrations are therefore representative of this distance from the kerb. Roadside concentrations for urban major road links (A-roads and motorways) only are reported and included in this report.

Figure 4.9 - Calibration of NO_x PCM RKM model, 2021 ($\mu\text{g m}^{-3}$, as NO₂)

4.4 NO₂ Modelling

4.4.1 Introduction

Maps of estimated annual mean NO₂ concentrations (Figure 4.1 and Figure 4.2) have been calculated from the modelled NO_x concentrations using a calibrated version of the updated oxidant-partitioning model (Jenkin, 2004, 2012; Murrells *et al.*, 2008). This model uses representative equations to account for the chemical coupling of O₃, NO and NO₂ within the atmosphere. A key advantage of this approach for modelling NO₂ concentrations is that emission scenarios can be directly addressed by varying regional oxidant levels and/or primary NO₂ emissions.

4.4.2 The updated oxidant-partitioning model

The oxidant-partitioning model, developed by Jenkin (2004), enables NO₂ concentrations to be calculated using the following equations:

$$\begin{aligned} [\text{NO}_2] &= [\text{OX}] \cdot f(\text{NO}_x) & (i) \\ [\text{OX}] &= f\text{-NO}_2 \cdot [\text{NO}_x] + [\text{OX}]_B & (ii) \end{aligned}$$

Where [OX] is the total oxidant (the sum of NO₂ and O₃), f-NO₂ is the primary NO₂ emission fraction (defined as the proportion of NO_x emitted directly as NO₂), [OX]_B is the regional oxidant and f(NO_x) is a function, the value of which is determined by the concentration of NO_x. NO_x, NO₂, O₃ and OX are all expressed as ppb in these equations: 1 ppb of O₃ = 2 $\mu\text{g m}^{-3}$; 1 ppb of NO₂ = 1.91 $\mu\text{g m}^{-3}$. By convention when NO_x is expressed in $\mu\text{g m}^{-3}$ it is expressed as " $\mu\text{g m}^{-3}$ as NO₂" therefore 1 ppb of NO_x = 1.91 $\mu\text{g m}^{-3}$ of NO_x as NO₂.

In Jenkin (2004), [NO₂]/[OX] (i.e. f(NO_x)) was calculated using two equations, one of which represented background locations and the other roadside locations. Updated equations for [NO₂]/[OX]

were subsequently developed in Murrells *et al.* (2008). More recently, (Jenkin, 2012) found that short term variability in NO_x concentrations is a major cause of the scatter in the relationship between [NO₂]/[OX] and [NO_x]. The ratio of the upper to the lower quartile of hourly concentrations has been found to be a good indicator of this variability. The ratio increases with decreasing NO_x concentrations at roadside and background sites. This dependence has been used to interpolate between equations based on a constant NO_x quartile ratio. This led to two equations for calculating [NO₂]/[OX], one of which represents background locations and the other roadside locations. These are the equations that are currently used in the modelling. These are an improvement over the equations presented in (Murrells *et al.*, 2008) because the background equation requires less adjustment in the background adjustment calibration and the roadside equation enables linear calibration adjustment for roadside.

Jenkin (2012) presented two equations for calculating [NO₂]/[OX] as a function of [NO_x] (i.e. $f(\text{NO}_x)$). These are:

- One background relationship, which has been derived using data from background sites.
- One roadside relationship, which has been derived using data from roadside sites.

The two relationships are presented in Table 4.4 below.

Table 4.4 - The two relationships in the updated oxidant-partitioning model (Jenkin, 2012)

PCM Category	Relationship (where $y = [\text{NO}_2]/[\text{OX}]$ and $x = [\text{NO}_x]$, in ppb)
Background	$y = -2.5124\text{E-}13x^6 + 1.5805\text{E-}10x^5 - 4.1429\text{E-}08x^4 + 5.8239\text{E-}06x^3 - 4.8076\text{E-}04x^2 + 2.5916\text{E-}02x$
Roadside	$y = -2.0901\text{E-}13x^6 + 1.5001\text{E-}10x^5 - 4.2894\text{E-}08x^4 + 6.2659\text{E-}06x^3 - 5.0720\text{E-}04x^2 + 2.5322\text{E-}02x$

The following sections describe the method for calculating an average regional oxidant value for the UK (Section 4.4.3), local oxidant calculations for background and roadside locations (Section 4.4.4), calculating [NO₂]/[OX] in the PCM model and how the updated oxidant-partitioning model has been applied in the UK to background and roadside locations (Section 4.4.5).

4.4.3 UK regional oxidant

A fixed regional oxidant value for the whole of the UK has been used. The regional oxidant value for 2021 was calculated to be 31.4 ppb. This value was derived from an analysis of annual mean data for O₃, NO₂ and total nitrogen oxides (NO_x) at 57 AURN sites. These sites were selected using the criterion that the annual mean [NO_x] in 2021 was less than or equal to 25 ppb, so that the contribution to [OX] derived from primary NO₂ was comparatively small. A constant $f\text{-NO}_2$ value of 0.093 was used to correct for the contribution from local oxidant.

4.4.4 Local oxidant calculations

Local oxidant is calculated in the updated oxidant-partitioning model as:

$$\text{Local oxidant} = f\text{-NO}_2 \cdot [\text{NO}_x] \quad (iv)$$

Where $f\text{-NO}_2$ is the fraction of NO_x emissions emitted as primary NO₂ (by volume). Therefore, to calculate local oxidant levels, the $f\text{-NO}_2$ levels from different local sources need to be understood. In general, it is possible to make a distinction between $f\text{-NO}_2$ from road traffic sources and $f\text{-NO}_2$ from non-road traffic sources. $f\text{-NO}_2$ from road traffic sources is thought to have risen during the early 2000s, although this trend displays considerable variation with location (Air Quality Expert Group (AQEG), 2007; Carslaw *et al.*, 2011). By comparison, $f\text{-NO}_2$ from non-traffic sources has remained relatively constant with time.

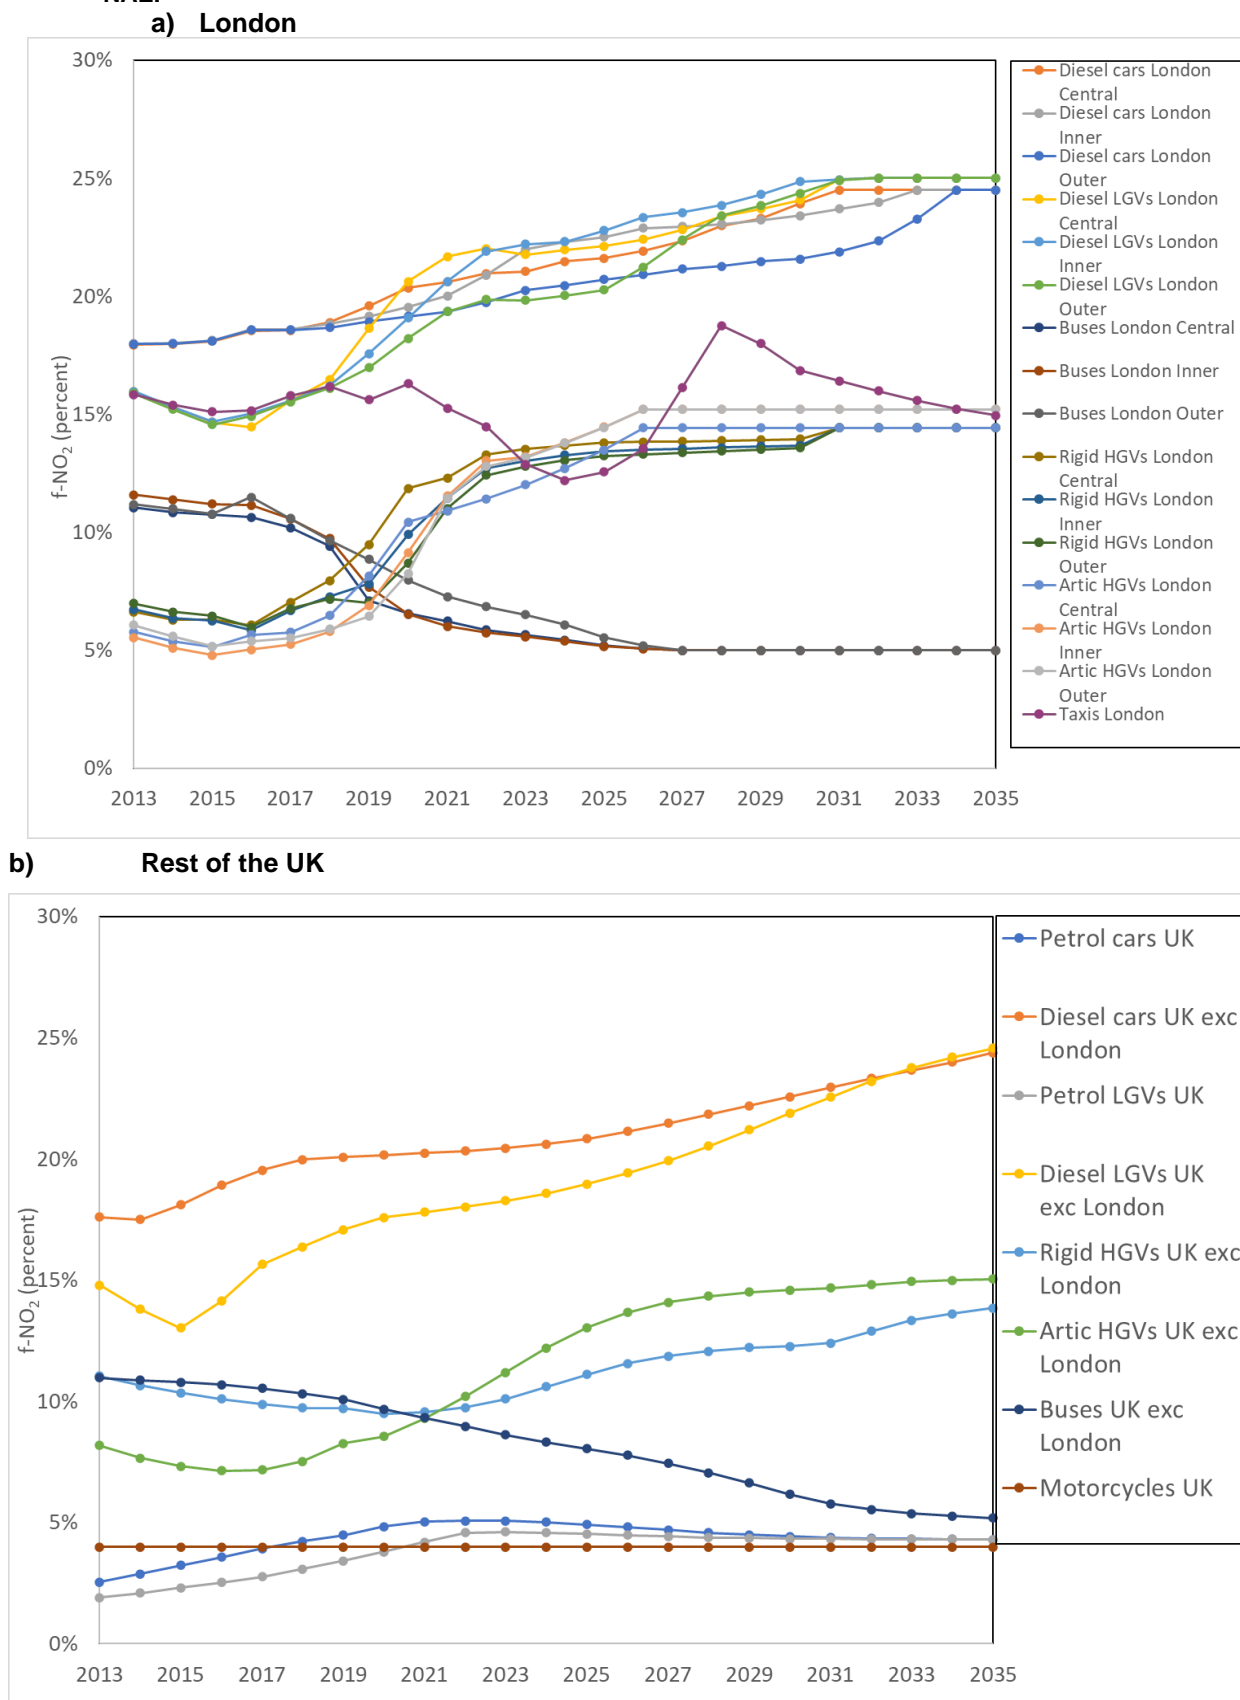

4.4.4.1 $f\text{-NO}_2$ for road traffic sources on individual road links

Figure 4.10 shows fleet average $f\text{-NO}_2$ projections by vehicle type for London and the rest of the UK from the NAEI.

$f\text{-NO}_2$ for all petrol vehicles is very low (less than 5%). $f\text{-NO}_2$ for diesel cars and LGVs is much greater and is expected to increase somewhat in the future. $f\text{-NO}_2$ for HGVs and buses is lower and is also expected to decline for buses, HGVs however are expected to have an increase in $f\text{-NO}_2$. $f\text{-NO}_2$ projections for London show the impact of specific measures applied to London buses and the London

low emission zone (LEZ) and ultra-low emission zone (ULEZ). An update to primary NO₂ emission factors for road vehicles⁵ provides further information on $f\text{-NO}_2$ values.

Figure 4.10 - Fleet average $f\text{-NO}_2$ projections by vehicle type for a) London and b) rest of the UK from NAEI

⁵ [Primary NO₂ Emission Factors for Road Vehicles NAEI Base 2021 v3.pdf \(beis.gov.uk\)](#)

4.4.4.2 $f\text{-NO}_2$ for background sources

Table 4.5 shows the $f\text{-NO}_2$ values used for background sources in 2021. The non-road $f\text{-NO}_2$ values used for background calculations in Table 4.5 have been taken directly from (Jenkin, 2004), as there is little evidence that this has changed significantly over the past few years. The road traffic $f\text{-NO}_2$ values for background calculations have been calculated using the average of the major road link $f\text{-NO}_2$ values for each area type.

Table 4.5 - Local oxidant coefficients ($f\text{-NO}_2$) for background concentrations in 2021

DfT Area type ¹	Region	Non-road $f\text{-NO}_2$ for background calculations	Road $f\text{-NO}_2$ for background calculations
1	Central London	0.140	0.169
2	Inner London	0.128	0.161
3	Outer London	0.093	0.169
4	Inner Conurbations	0.093	0.161
5	Outer Conurbations	0.093	0.165
6	Urban (population > 250,000)	0.093	0.166
7	Urban (population > 100,000)	0.093	0.166
8	Urban (population > 25,000)	0.093	0.166
9	Urban (population > 10,000)	0.093	0.165
10	Rural	0.093	0.165

¹ Locations in Northern Ireland have been assigned area types according to how built up the local environment is because the DfT area types map does not cover Northern Ireland. A map of the distribution of DfT area types is included in Appendix 5 – Dispersion kernels for the area source model.

4.4.4.3 Local oxidant calculations

A map of local oxidant for the background NO_2 calculations was generated by splitting the background annual mean NO_x map into its two constituent components:

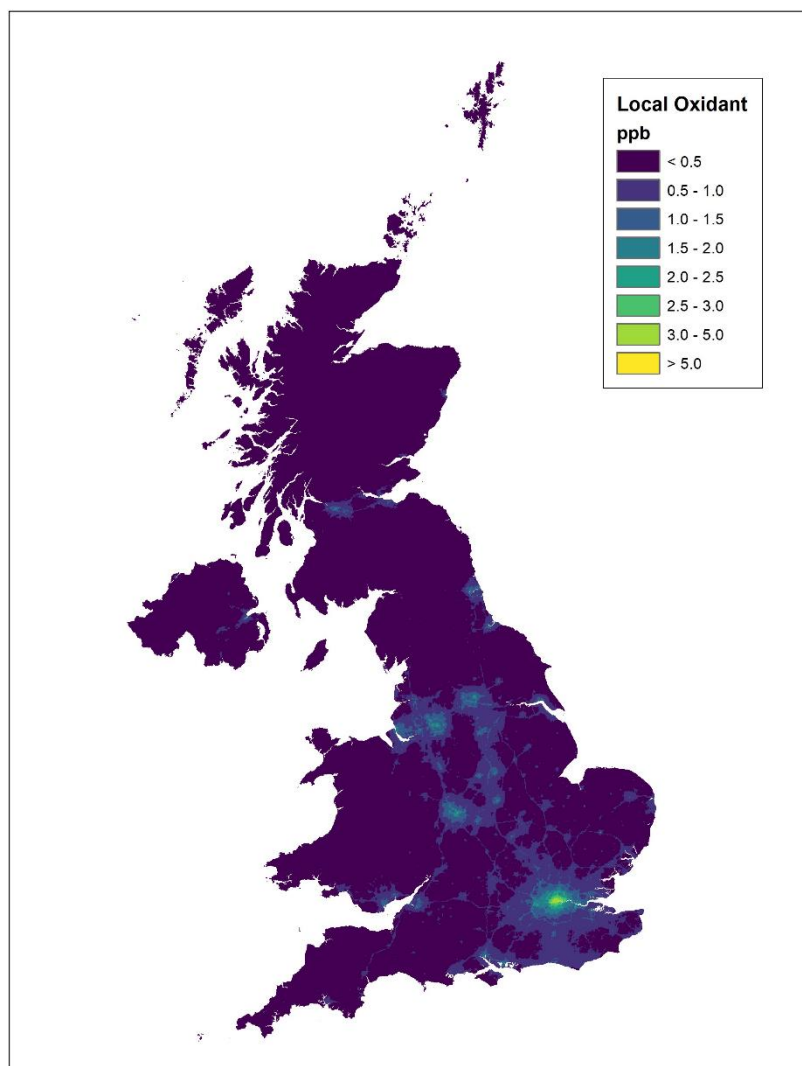

- NO_x from background non-road traffic emissions (includes rural background component)
- NO_x from background road-traffic emissions

These components were multiplied by the relevant $f\text{-NO}_2$ value from Table 4.5 and then added together to give a total local oxidant. Figure 4.11 shows the UK background local oxidant map for 2021.

Local oxidant on individual road links was calculated by splitting the total annual mean NO_x for the road link into its three constituent components:

- NO_x from background non-road traffic emissions (includes rural background component)
- NO_x from background road-traffic emissions
- Roadside increment NO_x concentrations from emissions on the specific road link under consideration

The background components were then multiplied by the relevant $f\text{-NO}_2$ value from Table 4.5 and the roadside increment NO_x was multiplied by the specific $f\text{-NO}_2$ calculated for that road link. These local oxidant values were then added together to give a total local oxidant for the road.

4.4.5 Calculating $[\text{NO}_2]/[\text{OX}]$ in the PCM model

As described in Section 4.4.2, two relationships for calculating $[\text{NO}_2]/[\text{OX}]$ have been derived in (Jenkin, 2012). The ratio of $[\text{NO}_2]/[\text{OX}]$ has been considered separately for background and roadside locations in this analysis as there are separate relationships for these locations. Background and roadside sites tend to behave differently because of differences in the 'age' of the NO_x at these locations.

4.4.5.1 Background

For background locations, the background relationship has been calibrated using data from AURN background sites for 2021. The calibration plot for background sites is shown in Figure 4.12. Figure 4.13 a and b show verification plots of measured NO_2 against modelled NO_2 calculated from measured NO_x using the uncalibrated background relationship and calibrated background relationship respectively. The agreement is better for the calibrated model. The background oxidant partitioning curves are only valid for annual mean NO_x concentrations up to $267.4 \mu\text{g m}^{-3}$ (as advised by (Jenkin, 2012)) hence NO_x concentrations above this value have been set to $267.4 \mu\text{g m}^{-3}$.

Figure 4.12 - Background NO₂ calibration curve (NB verification sites are shown for reference here, but were not used in calculating the calibration), 2021

Figure 4.13 - Verification of background relationship at background locations in 2021

a) Uncalibrated

b) Calibrated

4.4.5.2 Roadside

For roadside locations, the roadside relationship has been selected and an additional calibration has been applied using data from AURN roadside sites for 2021. The model has been calibrated by plotting the ratio of measured NO₂ to modelled NO₂ as a function of NO_x for each AURN roadside sites for 2021 and then fitting a straight line through these points. Figure 4.14 shows this ratio for each site and the straight line that was fitted through the data. The verification sites are also shown on this plot for reference although they were not used to calibrate the model.

Figure 4.14 - Roadside NO₂ calibration curve (NB verification sites are shown for reference here, but were not used in calculating the calibration factors), 2021

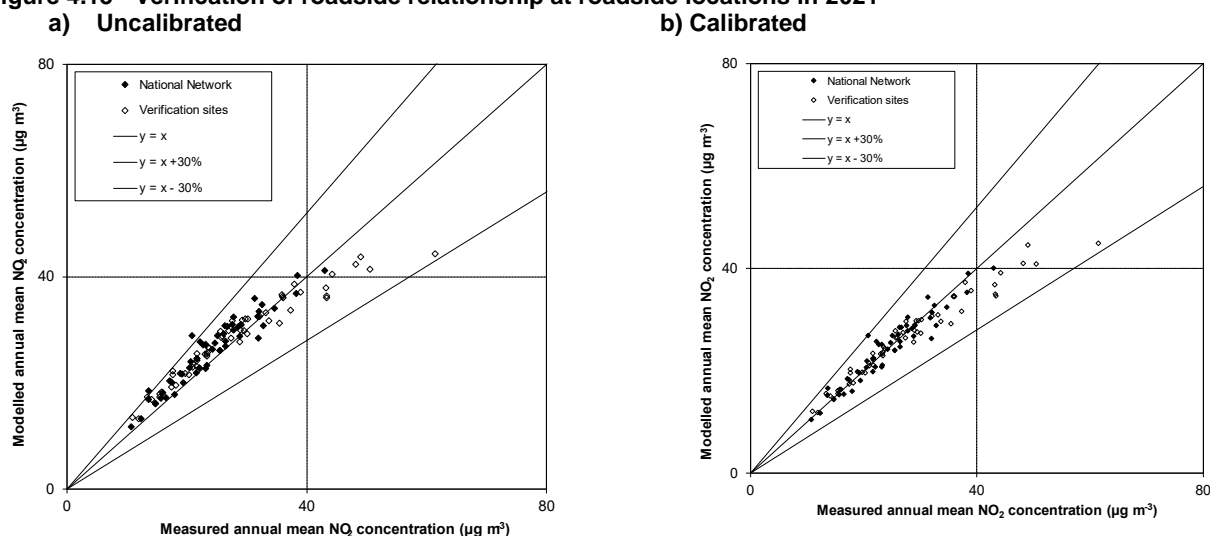

Figure 4.15a shows a verification plot of measured NO₂ against modelled NO₂ calculated from measured NO_x using the uncalibrated roadside relationship. Figure 4.15b shows the same information but using the calibrated roadside relationship. It is clear that the calibrated model provides a better fit to the monitoring data in the vicinity of the limit value of 40 $\mu g\ m^{-3}$. The roadside oxidant partitioning curves are only valid for annual mean NO_x concentrations up to 382 $\mu g\ m^{-3}$ (as advised by Jenkin (2012)) hence NO_x concentrations above this value have been set to 382 $\mu g\ m^{-3}$.

Figure 4.15 - Verification of roadside relationship at roadside locations in 2021

4.5 Results

4.5.1 Verification of mapped values

Figure 4.16 and Figure 4.17 show comparisons of modelled and measured annual mean NO_x and NO_2 concentration in 2021 at background monitoring site locations. Figure 4.18 and Figure 4.19 show similar comparisons for roadside sites. Both the national network sites used to calibrate the models and the verification sites are shown. Lines representing $y = x - 30\%$ and $y = x + 30\%$ are also shown (this is the AQSR data quality objective for modelled annual mean NO_2 and NO_x concentrations – see Section 1.5). There is no requirement under the AQSR to report modelled annual mean NO_x concentrations for comparison with limit values for the protection of human health (the NO_x limit value for the protection of vegetation only applies in vegetation areas). However, comparisons of modelled and measured NO_x concentrations and of the modelled NO_x concentrations with the data quality objectives are presented here alongside the comparisons for NO_2 . This provides an additional check on the reliability of the modelled estimates of NO_2 because the non-linear relationships between NO_x and NO_2 tend to cause modelled NO_2 concentrations to be relatively insensitive to differences between measured and modelled values of NO_x .

Summary statistics for the comparison between modelled and measured NO_x and NO_2 concentrations are listed in Table 4.6 and Table 4.7. The percentages of monitoring sites for which the modelled annual mean concentrations fall outside the data quality objectives is generally greater for NO_x than for NO_2 , for the reasons discussed above.

4.5.2 Source apportionment

Figure 4.16 and Figure 4.17 show the modelled NO_x source apportionment at AURN background and roadside sites respectively for 2021. This shows that while road transport is the dominant source at most locations, both background and roadside, contributions from other sectors such as domestic, commercial, off-road mobile machinery and industry are also significant at many sites. Contributions from aircraft and shipping are evident at some sites. No source apportionment is given for NO_2 because this is not a physically meaningful concept because of the non-linear relationship between NO_x and NO_2 .

Figure 4.20 - Annual mean NO_x source apportionment at background AURN monitoring sites in 2021 (area type of each site is shown in parenthesis after its name – see Table 4.5)

Figure 4.21 - Annual mean NO_x source apportionment at roadside AURN monitoring sites in 2021 (area type of each site is shown in parenthesis after its name – see Table)

5 SO₂

5.1 Introduction

5.1.1 Limit values

Two limit values for ambient SO₂ concentrations are set out in the AQSR (*legislation.gov.uk*, 2010) for the protection of human health. These limit values have been in force since 1st January 2005 and are specified as follows:

- An hourly concentration of 350 µg m⁻³, with 24 permitted exceedances each year
- A 24-hour mean concentration of 125 µg m⁻³, with 3 permitted exceedances each year.

A critical level for SO₂ for the protection of vegetation has also been specified in the AQSR:

- An annual mean and winter mean concentration of 20 µg m⁻³.

The critical level is designed to protect vegetation, so it only applies in vegetation areas as defined in the AQSR. The critical level has been in force since 2001.

5.1.2 Annual mean and winter mean modelling

A map of annual mean SO₂ concentrations for 2021 in vegetation areas has been calculated for comparison with the annual mean critical level described above; this map is shown in Figure 5.2. This map has been calculated by removing non-vegetation areas from the background SO₂ annual mean map and calculating the zonal mean of the 1 km x 1 km grid squares for a 30 km x 30 km grid so that it complies with the criteria set out in the AQSR. Mean concentrations on a 30 km x 30 km grid have been used to prevent the influence of any urban area appearing unrealistically large on adjacent vegetation areas. Thus, the modelled concentrations in vegetation areas should be representative of approximately 1000 km² as specified in the AQSR for monitoring sites used to assess concentrations for the vegetation critical level.

A map of winter mean SO₂ concentrations for the period October 2020 to March 2021 has also been calculated for comparison with the winter mean critical level and is shown in Figure 5.3. This map was calculated by multiplying the annual mean map for 2021 by the ratio between the average concentration measured at rural SO₂ monitoring sites during the 2020-2021 winter period and the annual concentration for 2021.

5.1.3 Modelling for comparison with the hourly and 24-hour limit values

Maps of the 99.73 percentile of the hourly mean and the 99.18 percentile of the 24-hour mean SO₂ concentrations have been calculated for 2021. They are shown in Figure 5.4 and Figure 5.5 respectively. These percentile concentrations correspond to the number of allowed exceedances of the 1-hour and 24-hour limit values for SO₂ described above.

5.1.4 Overview of the PCM model for SO₂

Figure 5.1 shows a simplified flow diagram of the PCM model for SO₂. A summary of the PCM model method, input, and assumptions for SO₂ is presented in Table 5.1.

Figure 5.1 - Flow diagram for PCM SO₂ model**Table 5.1 - PCM model method, input and assumptions summary for SO₂**

Heading	Component	Details
General	Pollutant	SO ₂
	Year	2021
	Locations modelled	Background
	Metric	Annual mean Winter Mean (2020-2021) 99.18 percentile daily mean 99.73 percentile hourly mean
Input data	Emission inventory	NAEI 2020 (scaled to 2021)
	Energy projections	Energy Projections 2021
	Road traffic counts	2021 (scaled from 2020 where not available)
	Road transport activity projections	DfT (2021) car sales projections, TfL fleet projections for London (2021)
	Road transport emission factors	COPERT 5.4(COPERT 5.4, 2020)
	Measurement data	2021
	Meteorological data	WRF (see Appendix 4 – WRF meteorology)
Model components	Regional	Constant derived from (Abbott & Vincent, 2006)
	Large point sources	339 sources modelled using ADMS 5.2
	Small point sources	PCM small points model
	ETS point sources	PCM small points model
	Large ETS point sources	78 sources modelled using ADMS 5.2
	Area sources	PCM dispersion kernels generated using ADMS 5.2. Time varying emissions for road transport and domestic sources. PCM small points model for industrial combustion emissions.
	Roadside increment	n/a

Heading	Component	Details
Calibration	Model calibrated?	No
	Number of background stations in calibration	n/a
	Number of traffic stations in calibration	n/a
Pollutant specific	Annual mean	Modelled directly
	Winter mean	Calculated from annual mean using scaling factor derived from ambient measurements at rural monitoring stations
	99.18 percentile daily mean	Maximum of values calculated by scaling and combining annual mean components or scaling and combining annual and percentile components
	99.73 percentile hourly mean	Maximum of values calculated by scaling and combining annual mean components or scaling and combining annual and percentile components

5.1.5 Outline of annual mean and winter mean modelling

The 1 km x 1 km annual mean background SO₂ concentration map has been calculated by summing the contributions from:

- Large point sources
- Small point sources
- Point sources with emissions estimates for air quality pollutants based on reported carbon emissions (ETS points)
- Local area sources
- Distant sources

The contributions from each of the above components were modelled as described in Section 5.3.1.

5.1.6 Outline of modelling for comparison with the hourly and 24-hour limit values

The 1 km x 1 km percentile SO₂ concentration maps have been calculated by combining the contributions from the same list of sources as for the annual mean modelling. Details of the method can be found in Section 5.3.2.

5.1.7 Chapter structure

This chapter describes modelling work carried out for 2021 to assess compliance with the SO₂ limit values and critical levels described above. Emission estimates for SO₂ are described in Section 5.2. Section 5.3.1 describes the SO₂ modelling methods for the annual and winter means. Section 5.3.2 describes the SO₂ modelling methods for the percentile metrics (for comparison with the hourly and 24-hour limit values). Model verification and source apportionment information are presented in Section 5.4.

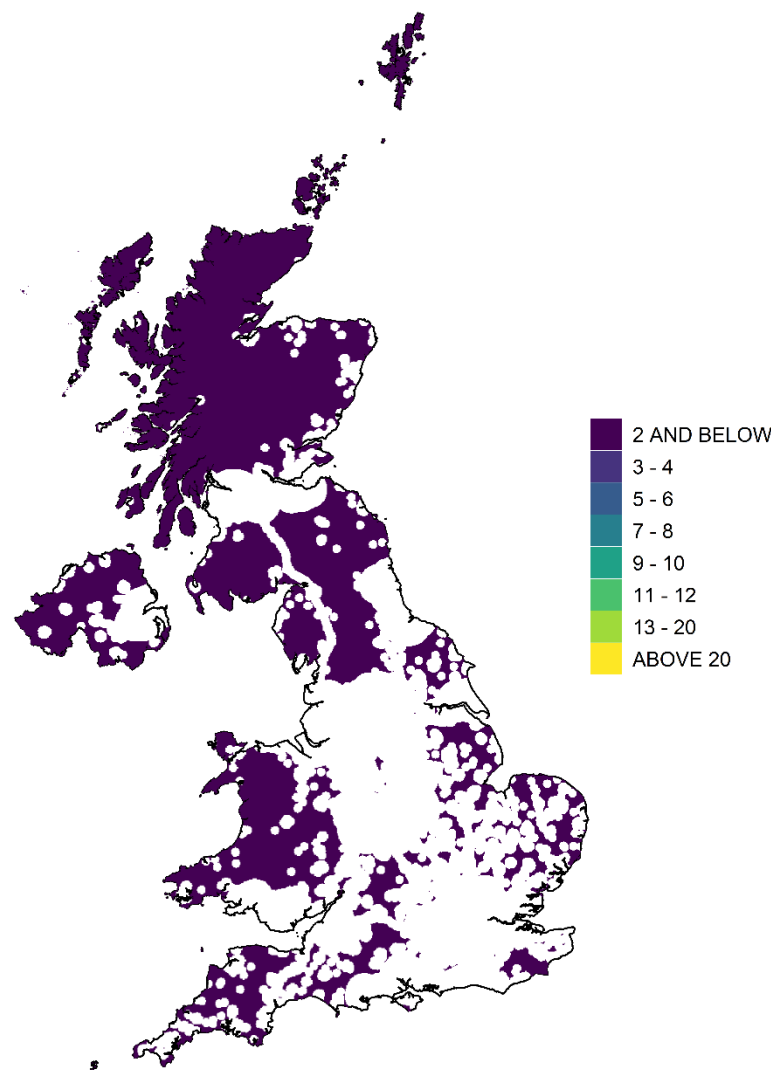

Figure 5.3 - Winter mean SO₂ concentration, 2020-2021 (µg m⁻³) in vegetation areas

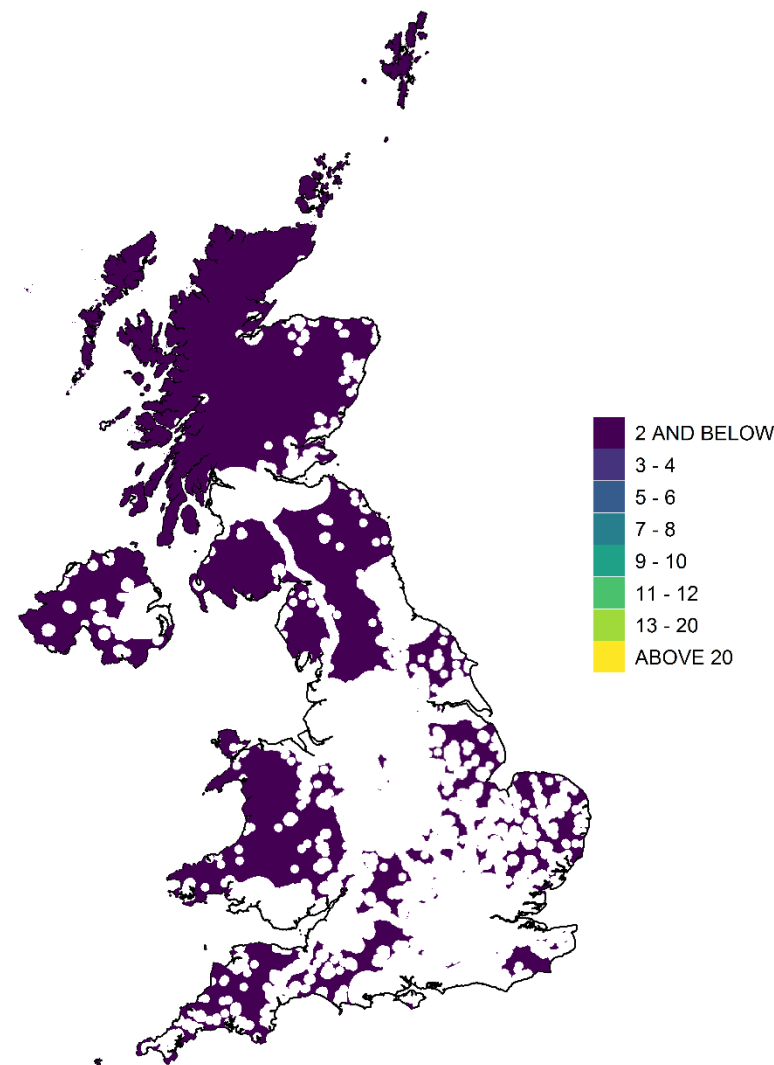

Figure 5.4 - 99.73 percentile of 1-hour mean SO₂ concentration, 2021 (µg m⁻³)

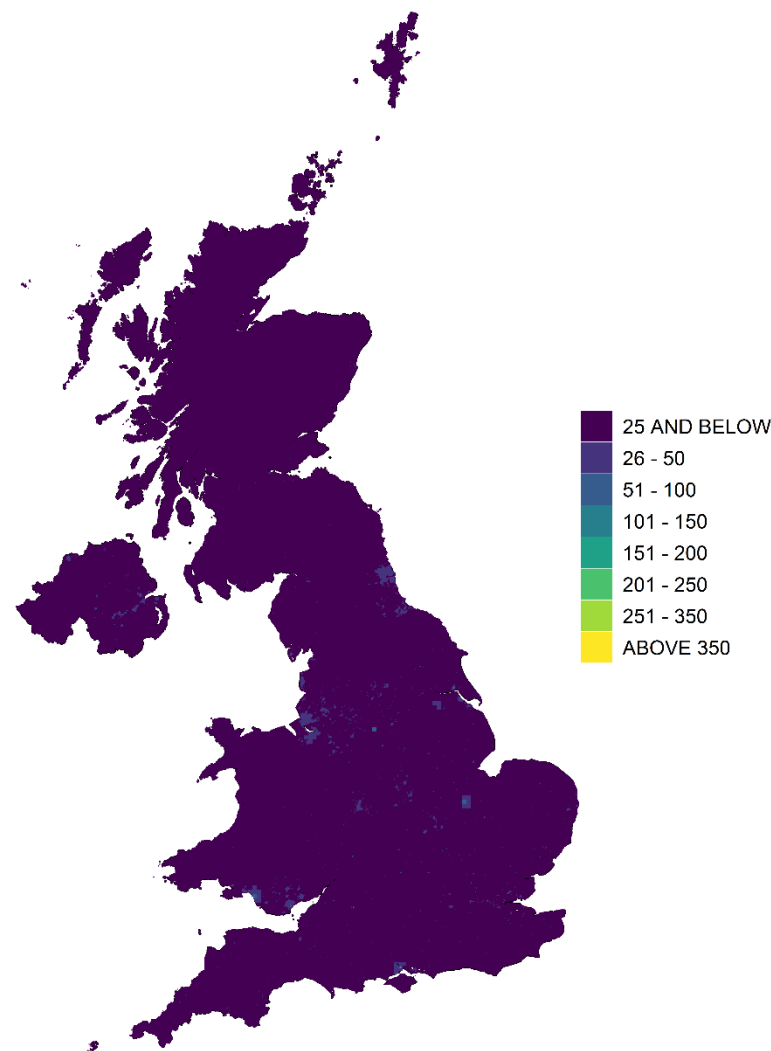

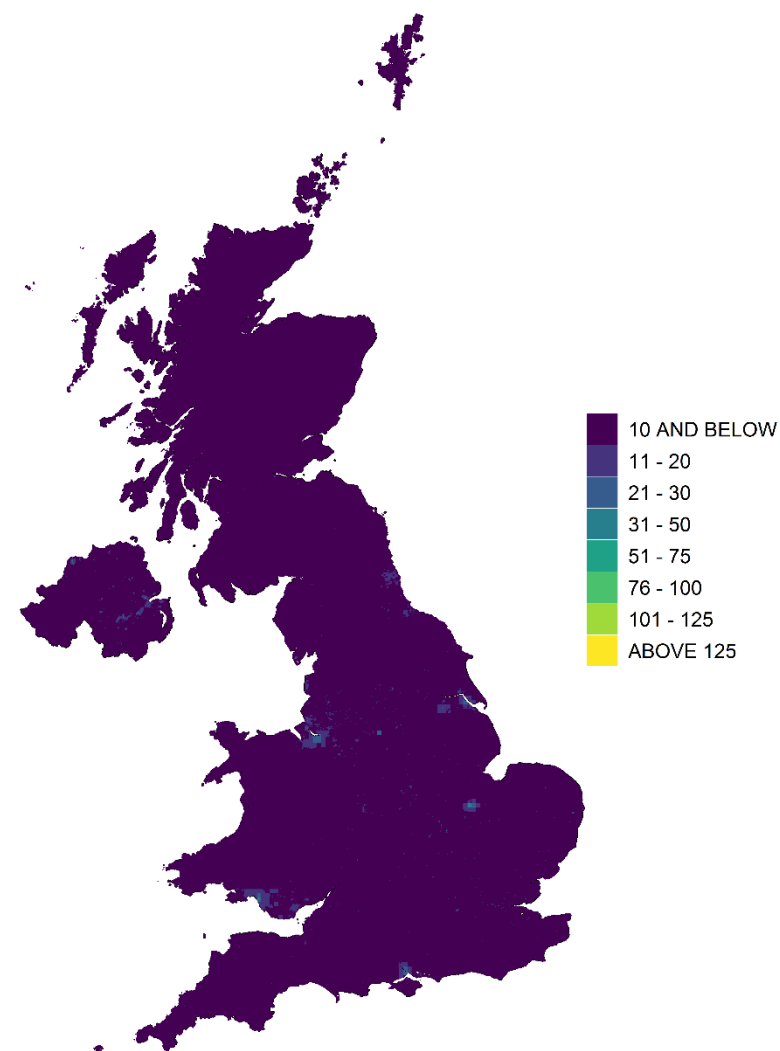

Figure 5.5 - 99.18 percentile of 24-hour mean SO₂ concentration, 2021 (µg m⁻³)

5.2 SO₂ emissions

Estimates of the emissions of SO₂ from the UK National Atmospheric Emissions Inventory 2020 (NAEI 2020) have been used in this study (Churchill *et al.*, 2022). Emissions projections have been provided by the NAEI (Personal communication from Ben Pearson, 2022) based on BEIS EEP 2021 energy and emissions projections (BEIS, 2022). The methods used to calculate projections 2020 to 2021 from taking the impact of the reduced activity levels in 2020 have been calculated as described in Section 3.

Figure 5.6 shows the UK total SO₂ emissions for 2021, with the coding described in Table 4.2. The figure shows that SO₂ emissions in 2020 are dominated four main sources:

- Combustion point sources (SNAP codes 1, 2 and 3)
- SNAP 2: Domestic combustion
- SNAP 3: Combustion in industry
- SNAP 4: Production processes (excluding quarrying and construction)

Figure 5.6 - Total UK SO₂ emissions for 2021 by SNAP code scaled using Covid factors from NAEI 2020

5.3 SO₂ modelling

The modelling methods for SO₂ were developed by (Abbott and Vincent, 1999, 2006). Emissions from point and area sources have been modelled separately and the results combined to produce the concentration maps.

5.3.1 Annual mean and winter mean modelling

5.3.1.1 SO₂ contributions from large and small point sources

Point sources in the NAEI 2020 have been classified as large if they fulfil either of the following criteria:

- Annual SO₂ emissions in the NAEI 2020 are greater than 500 tonnes for any given plant
- Stack parameters are already available for any given plant in the PCM stack parameters database (described in Section 4.3.1)

The contribution to ambient concentrations from large point sources were predicted using the dispersion model ADMS 5.2. Surface roughness varied at both the dispersion and meteorological sites depending on the area type as presented in Table A5.1.

Prior to 2016 the large points modelling for SO₂ used hourly emissions profiles for the power stations with the largest releases provided by the Environment Agency (England and Wales) or Scottish Power (Scotland). However, from 2016 onwards these data are not available because of changes to permit requirements under the Industrial Emissions Directive (IED, 2010). Previously (e.g. (Brookes *et al.*, 2017)) power station with large SO₂ releases for which hourly emissions profiles were not available, were modelled using time varying emissions profiles typical of electricity generation in summer and winter derived from the National Grid Seven Year Statement for 2011 (NETS, 2011). Given the lack of reported emissions profiles, these typical profiles have been applied to treat the time variation in emissions for power stations in the 2021 assessment modelling for SO₂ (Personal communication from Ben Pearson, 2022). The NAEI emissions for point sources for 2020 were scaled in order to provide values for 2021 as described in Section 3.

Concentrations resulting from emissions from other large SO₂ point sources were modelled using the projected NAEI emissions without time varying emissions. Closure of plant or activities are taken into account when deriving the source sector projection factors by subtracting the base year emissions associated with plant closure from the relevant source sector total for point sources for the NAEI base year. A total of 339 large point sources were modelled using emission release characteristics from the PCM stack parameters database.

Concentrations resulting from the projected emissions from small point sources were modelled using the small point source model described in Appendix 3 – Small point source model. In line with the method applied for the large point sources the NAEI 2020 emissions for small point sources have been scaled to 2021 using the same source sector specific projection factors applied to the large point sources. Any point sources in the NAEI base year which closed before the start or early in the current assessment year are removed from the modelling, based on recommendations from the NAEI team (Personal communication from Ben Pearson, 2022).

The NAEI 2020 includes point source emissions estimates derived from carbon emissions data reported under the EU-Emissions Trading Scheme (ETS), most recently described in (Tsagatakis *et al.*, 2022). These point sources are referred to as ETS points in this report. These derived air quality pollutant emissions are particularly uncertain and therefore in previous assessments (e.g. Brookes *et al.* (2017)) emissions were capped at reporting thresholds and treated as small point sources. For the 2016, 2017, 2018, 2019 and 2020 assessment (Brookes *et al.*, 2019b, 2019a, 2020, 2021; Pugsley *et al.*, 2022) the NAEI recommended treating the ETS points that have emissions greater than the large points modelling threshold as large points and not to apply a cap (Personal communication from Ben Pearson, 2022). The 2021 assessment continues this approach. Thus, based on the criteria for the treatment of large point sources described above, 78 ETS point sources were modelled as an additional set of large point sources (using the approach described above). ETS points that were not classified as large point sources were modelled using the SO₂ small points approach described above.

For the large point sources (including large ETS points), concentrations were predicted for 5 km x 5 km resolution receptor grids within a set of receptor areas (known as tiles), which together cover the UK. The size of the receptor areas was typically 100 km x 100 km, extending out to 150 km where appropriate. All sources within the receptor area and extending out 100 km from the tile border were assumed to influence concentrations within the receptor area. Concentrations have been

modelled using meteorological data for 2021 from the WRF numerical weather prediction modelling system, as described in Appendix 4 – WRF meteorology. The WRF model is a next-generation numerical weather prediction system developed by the US National Centre for Atmospheric Science (NCAR) (UCAR, 2020). This method accounts for spatial variation in meteorological parameters across the UK representing local dispersion characteristics within the PCM output. This approach ensures that the combined impact of several sources on ambient high percentile concentrations is estimated correctly. While not essential for the estimation of the annual mean, this method enables both the annual mean and high percentiles to be calculated from the same set of dispersion model calculations.

5.3.1.2 SO₂ contributions from local area sources

The 2021 area source SO₂ emissions maps have been calculated from the NAEI 2020 emissions maps following the method described in Section 4.3.5. Except for SNAP sector 3 (combustion in industry), the contribution to ambient SO₂ concentrations from area sources was calculated using a dispersion kernel approach. Concentrations are predicted for a 1 km x 1 km receptor grid, from the area source emissions within a 33 km x 33 km square surrounding each receptor. Dispersion kernels were calculated using ADMS 5.2 and hourly sequential meteorological data for 2021 from the WRF model. Modelling of the area sources is described in more detail in Appendix 5 – Dispersion kernels for the area source model.

Revised methods introduced in the 2012 compliance assessment modelling (Brookes *et al.*, 2013) for modelling the contributions to SO₂ from SNAP 2 (domestic and non-domestic combustion) and SNAP 3 (combustion in industry) area sources were used and have been described in Section 4.3.5.

The use of surrogate statistics for mapping area source emissions sometimes results in unrealistically large concentrations in some grid squares for a given sector. Emission caps have therefore been applied to certain sectors. The emission caps applied are given in Table 5.2.

Table 5.2 - Emissions caps applied to SO₂ sector grids

SNAP code	Description	Cap applied (t/a/km ²)
SNAP 8 (Shipping only)	Other Transport & Mobile Machinery	35

5.3.1.3 Deriving annual and winter mean concentration maps

The point source and area source contributions are summed without calibration, along with an estimate (0.19 µg m⁻³) of the contribution from the long-range transport of SO₂ sources from continental European sources to derive the annual mean concentration. The long-range transport contribution was derived by a linear least-squares fit between the measured and modelled concentrations (Abbott and Vincent, 2006). The model is not calibrated for SO₂ because modelled values provide a reasonably good fit to measured concentrations and to avoid the risk of overfitting for the high percentile metrics.

The map of winter mean SO₂ concentrations was derived from the annual mean map by multiplying with a factor of 1.2254, which is the ratio between the average concentration measured at rural SO₂ monitoring sites during the 2020-2021 winter periods and annual concentration for 2021.

Measured concentrations from UK Acid Gases and Aerosols Monitoring Network (AGANet) sites, selected rural and urban background sites in the national automatic monitoring networks were compared with the modelled results. A list of the additional sites used in model verification is included in Appendix 1 - Monitoring sites used to verify the mapped estimates. The comparison plot for 2021 is shown in Figure 5.7.

Figure 5.7 - Comparison plot for 2021 annual mean SO₂ concentration

5.3.2 Modelling percentile concentrations for comparison with the 1-hour and 24-hour limit values

The methodology to produce the percentile maps is based on research on combining concentrations arising from area and industrial sources undertaken for the Environment Agency (Abbott and Vincent, 2006). This methodology aims to derive an estimate of the percentile concentrations at locations distant from the industrial sources. A weighted regression analysis was carried out by Abbott and Vincent, assuming that the variance of the residuals was proportional to the modelled concentration.

The regression model was of the form:

$$C_{measured} = \max \left[\frac{Ac_{modelled_industrial, \%ile} + 2(c_{modelled_area} + c_{long_range})_{annual}}{2Ac_{modelled_industrial, annual} + k(c_{modelled_area} + c_{long_range})_{annual}} \right]$$

The constant A was obtained from the regression analysis. The background multiplier factor, k , was derived from monitoring data. The factor “2”, used to scale the $(c_{modelled_area} + c_{long_range})_{annual}$ and $c_{modelled_industrial, annual}$ components, has been shown to be a robust factor that allows short-term average concentrations to be estimated from modelled annual mean concentrations arising from non-industrial or industrial sources (Abbott, Stedman and Bower, 2005). Table 5.3 presents the A and k factors used in the derivation of the maps.

Table 5.3 - Factors for percentile models

Metric	Constant (A)	Background multiplier factor (k)	C_{long_range}
99.73 percentile of 1-hour values	1.09	10.1	0.19
99.18 percentile of 24-hour values	1.23	3.3	0.19

The justification for treating industrial point sources and area emissions separately is because peaks in high percentile modelled contributions from point sources may not coincide with peaks in high percentile background concentrations – a problem that is more pronounced in emissions from large industrial point sources because the meteorological conditions that give rise to high concentrations from tall stacks can be very different from those that produce high concentrations from emissions at low level. Figure 5.8 and Figure 5.9 provide an intermediate quality check at selected rural and urban background sites which form part of the national network.

Figure 5.8 - Comparison plot for 2021 99.73 percentile of 1-hour mean SO₂ concentrations**Figure 5.9 - Comparison plot for 2021 99.18 percentile of 24-hour mean SO₂ concentrations**

An alternative method was used to derive the high percentile concentrations in Northern Ireland. This was required because area sources, predominately emissions from domestic solid and liquid fuel use,

make a more significant contribution to observed high percentile concentrations in Northern Ireland than in the rest of the United Kingdom. Additionally, the smaller number of point sources in Northern Ireland means that these sources make a much smaller contribution to the observed high percentile concentrations.

Maps of high percentile concentrations in Northern Ireland have been calculated from the mapped annual mean SO₂ concentrations using a linear least-squares fit between measured annual mean and measured high percentile concentrations in Northern Ireland over the period from 2008 to 2021 at AURN National Network and Ricardo Calibration Club monitoring sites. Ten years of data have been used to enable the calculation of robust estimates. Figure 5.10 and Figure 5.11 show the relationship between the annual mean and the 99.73 percentile of 1-hour mean values and the 99.18 percentile of 24-hour mean values at the sampling sites in Northern Ireland.

The equations used to derive the high percentile maps are:

Predicted 99.73%ile in Northern Ireland = $8.7229 \times \text{Modelled Annual Mean} + 0.7632 \mu\text{g m}^{-3}$, and

Predicted 99.18%ile in Northern Ireland = $4.2194 \times \text{Modelled Annual Mean} + 0 \mu\text{g m}^{-3}$.

Figure 5.10 - Relationship between mean concentration and 99.73 percentile of 1-hour concentrations at sampling sites in Northern Ireland, 2008-2021

Figure 5.11 - Relationship between mean concentration and 99.18 percentile of 24-hour concentrations at sampling sites in Northern Ireland, 2008-2021

5.4 Results

5.4.1 Verification of mapped values

Figure 5.12, Figure 5.13 and Figure 5.14 show comparisons of modelled and measured annual mean, 99.73 percentile of 1-hour mean and 99.18 percentile of 24-hour mean SO₂ concentrations in 2021 at monitoring site locations in the UK. Both the national network sites and the verification sites are shown. Lines representing $y = x - 30\%$ and $y = x + 30\%$ or $y = x - 50\%$ and $y = x + 50\%$ are also shown (the AQSR data quality objective for modelled annual mean and percentile SO₂ concentrations respectively – see Section 1.5). The 'National Network Sites' include AURN sites and (for annual means only) Acid Gases and Aerosols Monitoring Network (AGANet) sites. 'Verification sites' include ad-hoc monitoring sites and Ricardo Calibration Club monitoring sites. A complete list of the AURN sites used is presented in Data flow C of the e-Reporting submission for 2021 (*UK-Air*, 2022). Details of other verification sites are presented in Table A1.2 of Appendix 1 - Monitoring sites used to verify the mapped estimates which also includes sites maintained by Hanson Building Products Ltd.

Figure 5.12 - Verification of annual mean SO₂ model, 2021**Figure 5.13 - Verification of 99.73 percentile of 1-hour mean SO₂ model, 2021****Figure 5.14 - Verification of 99.18 percentile of 24-hour mean SO₂ model, 2021**

Summary statistics comparing modelled and measured SO₂ concentrations for annual mean, 99.73 percentile of hourly values and 99.18 percentile are listed in Table 5.4, Table 5.5 and Table 5.6, respectively.

For the National Network (comprising sites belonging to the combined the AURN and AGANet networks) the measured annual average concentration over all these sites ($0.79 \mu\text{g m}^{-3}$) did not compare favourably with the modelled concentrations predicted at the same sites ($2.03 \mu\text{g m}^{-3}$). Only about 15% of the sites fell within the DQO. Reasons for poor performance may include very local emission sources not adequately represented in the emission inventory. However, despite the poor agreement, it should be noted that both the measurements and modelled estimates are significantly below the limit values for all metrics. Note that the 1 km x 1 km grid annual mean map is not compared directly with the annual mean limit value; the zonal mean of the 1 km x 1 km grid squares in vegetation areas has been calculated for a 30 km x 30 km grid, as discussed above.

For the 99.73 percentile of 1-hour mean concentrations and the 99.18 percentile of 24-hour mean concentrations there is again reasonable agreement between measured and modelled means at the

AURN sites and quality check sites (AURN). Due to the more generous data quality objectives for the short-term percentile concentrations, fewer sites, as expected, will fall outside the DQO limits.

Table 5.4 - Summary statistics for comparison between modelled and measured annual mean concentrations of SO₂ at background sites

	Mean of measurements (µg m ⁻³)	Mean of model estimates (µg m ⁻³)	R ²	% of sites outside DQO of ±30%	Number of sites in assessment

Verification Sites	6.03	12.93	0.36	71.4%	14

c includes measurement data from sites in Defra's AURN only

5.4.2 Source apportionment

Figure 5.15 shows the source apportionment for modelled annual mean concentrations of SO₂ at AURN monitoring sites for 2021. Measured annual mean concentrations at each site are shown for reference. The figure shows that annual mean SO₂ concentrations at most sites are dominated by contributions from industrial emissions treated as either point sources or area sources. Some sites also have significant contributions from shipping and domestic sources of emissions.

Figure 5.15 - Annual mean SO₂ source apportionment at AURN monitoring sites in 2021 (the area type of each site is shown in parenthesis after its name – see Table 4.5)

6 PM₁₀

6.1 Introduction

6.1.1 Limit values

Two limit values for ambient PM₁₀ concentrations are set out in the AQSR ([legislation.gov.uk](https://www.legislation.gov.uk), 2010). These have been specified for the protection of human health and came into force from 01/01/2005. These limit values are:

- An annual mean concentration of 40 µg m⁻³.
- A 24-hour mean concentration of 50 µg m⁻³, with 35 permitted exceedances each year

Results of the assessment in terms of comparisons of the modelled concentrations with the annual mean and 24-hour mean limit values for PM₁₀ have been reported in e-Reporting Data flow G which is published on UK-Air ([UK-Air](https://www.uk-air.org.uk), 2022).

6.1.2 Annual mean model

Maps of annual mean PM₁₀ in 2021 at background and roadside locations are shown in Figure 6.1 and Figure 6.2. These maps have been calibrated using PM₁₀ measurements within the national network for which co-located PM_{2.5} measurements are also available. The models for PM₁₀ and PM_{2.5} are designed to be fully consistent. Each component is either derived from emission estimates for PM₁₀ or PM_{2.5} or the contributions to the fine and coarse particle size fractions are estimated separately. This enables us to carry out an additional sense check that the calibration parameters for the two pollutants are reasonably consistent. Measurements from national network sites without collocated PM_{2.5} measurements have been used as an additional verification dataset (and similarly PM_{2.5} sites without PM₁₀ have been used as an additional verification dataset for PM_{2.5}). Measurements from gravimetric instruments within the national network and from non-national network sites have also been used to verify the mapped estimates. Appropriate scaling factors have been applied prior to comparison where required.

A detailed description of the Pollution Climate Mapping (PCM) models for PM in 2004 has been provided by (Stedman *et al.*, 2007). The methods used to derive the maps for 2021 are largely the same as was adopted for the 2020 maps described in (Pugsley *et al.*, 2022).

Table 6.1 - PCM model method, input and assumptions summary for PM₁₀

Heading	Component	Details
General	Pollutant	PM ₁₀
	Year	2021
	Locations modelled	Background and traffic locations
	Metric	Annual mean
Input data	Emission inventory	NAEI 2020 (scaled to 2021)
	Energy projections	Energy Projections 2021
	Road traffic counts	2021 (scaled from 2020 where not available)
	Road transport activity projections	DfT (2021) car sales projections, TfL fleet projections for London (2021)
	Road transport emission factors	COPERT 5.4(COPERT 5.4, 2020)
	Measurement data	2021
	Meteorological data	WRF (see Appendix 4 – WRF meteorology)
	Regional	See details under “pollutant specific” heading
Model components	Large point sources	414 sources modelled using ADMS 5.2
	Small point sources	PCM small points model
	ETS point sources	PCM small points model
	Large ETS point sources	65 sources modelled using ADMS 5.2
	Area sources	PCM dispersion kernels generated using ADMS 5.2. Time varying emissions for road transport and domestic sources. PCM small points model for industrial combustion emissions.

Heading	Component	Details
Calibration	Roadside increment	PCM Roads Kernel Model using ADMS-Roads 5.0
	Model calibrated?	Yes
	Number of background stations in calibration	46 (stations with both PM ₁₀ and PM _{2.5})
	Number of traffic stations in calibration	15 (stations with both PM ₁₀ and PM _{2.5})
Pollutant specific	Secondary inorganic aerosol	Interpolated from SO ₄ , NO ₃ and NH ₄ measurements at a network of 26 rural stations, scaling factors applied for size fraction, bound water and counterions
	Secondary organic aerosol	Results from the NAME model for 2008
	Regional primary particles	Calculated using the TRACK receptor oriented, Lagrangian statistical model
	Regional calcium rich dusts from re-suspension of soils	Modelled using information on land cover (bare soil, root and cereal crops) and dispersion kernel incorporating emissions and dispersion processes
	Regional iron rich dusts from re-suspension	Assigned a constant value of 0.5 µg m ⁻³
	Iron rich dusts from re-suspension due to vehicle activity	Modelled using information on vehicle movements on major roads (HDV) and dispersion kernel incorporating emissions and dispersion processes
	Sea Salt	Interpolated measurements of Cl, scaling factor applied for sea water composition
	Residual	A value assigned based on best fit to PM ₁₀ and PM _{2.5} measurements: zero, no residual required

6.1.4 Outline of the annual mean model

The maps of annual mean background PM₁₀ concentrations have been calculated by summing contributions from different sources:

- Secondary inorganic aerosol (sulphate, nitrate and ammonium, formed in the atmosphere by chemical reactions from gaseous species (SO₂, NO_x and NH₃))
- Secondary organic aerosol (non-volatile organic molecules formed in the atmosphere from volatile organic compounds by chemical oxidation reactions)
- Large point sources of primary particles
- Small point sources of primary particles
- Point sources with emissions estimates for air quality pollutants based on reported carbon emissions (ETS points)
- Regional primary particles
- Area sources related to domestic combustion
- Area sources related to combustion in industry
- Area sources related to road traffic
- Other area sources
- Regional calcium rich dusts from re-suspension of soils
- Regional iron rich dusts from re-suspension
- Iron rich dusts from re-suspension due to vehicle activity
- Sea salt
- Residual (zero)

The concentrations of many of these components have been estimated separately for the fine and coarse fraction. This enables a consistent method to be adopted for estimation of PM₁₀ (the sum of the fine and coarse fractions) and PM_{2.5} (fine fractions only). These component pieces are aggregated to a single 1 km x 1 km background PM₁₀ grid. An additional roadside increment is added for roadside locations.

The results from the annual mean model can be directly compared with the annual mean limit value in order to carry out the air quality assessment.

6.1.5 Compliance assessment modelling for the 24-hour limit value

24-hour mean concentrations have not been explicitly modelled for comparison with the 24-hour limit value. An annual mean concentration of 31.5 µg m⁻³, gravimetric has been taken to be equivalent to 35 days with 24-hour mean concentrations greater than 50 µg m⁻³ gravimetric (the 24-hour limit value) for 2021. A modelled annual mean concentration of greater than this value has been taken to indicate a modelled exceedance of the 24-hour mean limit value. This approach was initially proposed by (Stedman, Bush, *et al.*, 2001) who recommended a value of 31.5 µg m⁻³ based on an analysis of monitoring data for the period 1992 to 1999. An analysis of monitoring data (Brookes *et al.*, 2011) showed that the value of 31.5 µg m⁻³ was still valid up to and including 2010. An analysis of monitoring data for 2021 shown in Figure 6.4 showed that this value is appropriate for 2021.

Figure 6.4 - The relationship between the 90th percentile of 24-hour mean PM₁₀ concentration and annual mean concentration (µg m⁻³) for 2021

6.1.6 Chapter structure

This chapter describes modelling work carried out for 2021 to assess compliance with the PM₁₀ limit values described above. Emission estimates for primary PM are described in Section 6.2, Section 6.3 describes the PM₁₀ modelling methods, the modelling results are presented in Section 6.4. The methods used to subtract the contribution from natural sources (sea salt) and the results of this subtraction are presented in Section 6.5.

6.2 PM₁₀ emissions

Estimates of the emissions of primary PM from the UK National Atmospheric Emission Inventory 2020 (NAEI 2020) have been used in this study (Churchill *et al.*, 2022). Emissions projections have been provided by the NAEI (Personal communication from Ben Pearson, 2022) based on BEIS EEP 2021 energy and emissions projections (BEIS, 2022). The methods used to calculate projections 2020 to 2021 from taking the impact of the reduced activity levels in 2020 and 2021 have been calculated as described in Section 3.

Figure 6.5 shows UK total PM₁₀ emissions for 2021, with the coding described in Table 4.2. Figure 6.5 shows that PM₁₀ emissions in 2021 include contributions from a wide range of different source sectors. The figure shows that PM₁₀ emissions in 2021 the largest contributions are from three sources:

- SNAP 4: Production processes
- SNAP 2: Domestic combustion
- SNAP3: Industrial combustion

The methods used to calculate ambient concentrations from the estimates of primary PM emissions are described below for point, area, road link and regional sources.

Figure 6.5 - Total UK PM₁₀ emissions for 2021 by SNAP code scaled using covid factors from NAEI 2020

6.3 PM₁₀ modelling

6.3.1 Contributions from secondary inorganic aerosol

Maps of secondary inorganic aerosol (SIA) concentrations across the UK have been calculated from rural measurements of sulphate, nitrate and ammonium concentrations by interpolation, followed by the application of scaling factors derived from mass closure modelling. Monthly measurements are available for 26 rural monitoring sites within the UKEAP AGANet and NAMN networks for 2021 (some sites were excluded due to low data capture). The measurement method used within the AGANet was changed at the beginning of 2016. This revised method typically results in higher measured concentrations of sulphate and nitrate (Tang *et al.*, 2015). Concentration surfaces on a 5 km x 5 km grid were calculated from the measurement data using inverse distance weighting (IDW).

These secondary components were then split into fine and coarse using coefficients derived with reference to the detailed PM sampling carried out during the PUMA campaign at the University of Birmingham urban background monitoring site in June and July 1999 (Harrison and Yin, 2006) and summarised by Kent, Grice, Stedman, Bush, et al. (2007). Fine PM is used to describe PM_{2.5} and coarse PM is used to describe PM_{2.5-10} in this report.

The secondary components were also scaled according to 'bound water' associated with the mass of water embedded within the particles (Air Quality Expert Group (AQEG), 2005). Particle bound water is associated with the hygroscopic anions (Harrison and Yin, 2006). Therefore, a particle bound water scaling factor of 1.279 has been applied to the SIA components to account for the additional mass of water associated with the particulate matter (see Table 6.2). The factor for coarse mode nitrate is higher as this includes the mass of the counter-ion (sodium or calcium).

The split between coarse and fine nitrate was revised for the 2006 modelling assessment with reference to measurement data from the TRAMAQ (Abdalmogith, Harrison and Derwent, 2006) and Birmingham (Harrison and Yin, 2006) studies. The revised method has also been used in this assessment. The split between fine and coarse PM is simple to interpret for most PM constituents but is more complex for nitrate PM because there are two modes. The fine nitrate mode consists of ammonium nitrate, which is volatile, and is all in the fine PM_{2.5} fraction. The coarse mode consists of sodium nitrate, which is split half and half between fine PM_{2.5} and coarse PM_{2.5-10} fractions (Abdalmogith, Harrison and Derwent, 2006). Measurement data from the Birmingham study (Harrison and Yin, 2006) shows that the fine PM_{2.5} nitrate to coarse PM_{2.5-10} ratio was 3.5:1. Thus the fine mode nitrate to coarse mode nitrate ratio was 1.25:1. The factors for nitrate in Table 6.2 have been derived from a combination of this factor of 1.25 and the half and half split of the coarse mode nitrate into the fine PM_{2.5} and coarse PM_{2.5-10} fractions.

Table 6.2 - Scaling factors for size fraction, bound water and counter ion mass for secondary inorganic and organic aerosol

Pollutant	Size fraction	Scaling factor for size fraction	Scaling factor for bound water and counter-ion mass
SO ₄	Fine	0.94	1.279
	Coarse	0.06	1.279
NO ₃	Fine mode	0.556	1.279
	Coarse mode fine	0.222	1.60
	Coarse mode coarse	0.222	1.60
NH ₄	Fine	0.97	1.279
	Coarse	0.03	1.279
SOA	Fine	1.00	1.0
	Coarse	0.0	1.0

6.3.2 Contributions from secondary organic aerosol

Estimates of annual mean secondary organic aerosol (SOA) concentrations in 2008 from the NAME Model on a 20 km x 20 km grid across the UK have been provided by Redlington and Derwent (2013). SOA concentrations are assumed to have remained at 2008 levels in 2021 and this is reasonable because the majority (about 80% as a population-weighted mean) of the SOA is from biogenic sources. NAME is a Lagrangian dispersion model that simulates the dispersion, chemistry and deposition processes occurring in the atmosphere, utilising three dimensional meteorological fields from the Met Office Unified Model (Redlington *et al.*, 2009). The chemistry scheme includes the formation of anthropogenic and biogenic SOA, details of the scheme can be found in Redlington and Derwent (2013). The SOA component has been assumed to fall within the PM_{2.5} fraction.

6.3.3 Contributions from large and small point sources

Contributions to ground level annual mean primary PM concentrations from large point sources (those with annual emission greater than 200 tonnes, or for which emission release characteristics are known) in the NAEI 2020 have been estimated by modelling each source explicitly using the atmospheric dispersion model ADMS 5.2. Concentrations have been modelled using meteorological data for 2021 from the WRF numerical weather prediction modelling system, as described in Appendix 4 – WRF meteorology. The WRF model is a next-generation numerical weather prediction system

developed by the US National Centre for Atmospheric Science (NCAR)(UCAR, 2020). This method accounts for spatial variation in meteorological parameters across the UK representing local dispersion characteristics within the PCM output. Hourly sequential meteorological data for 2020 from WRF was applied. Surface roughness varied at both the dispersion and meteorological sites depending on the area type as presented in Table A5.1. Concentrations were calculated for a 99 km x 99 km square composed of a regularly spaced 1 km x 1 km resolution receptor grid. Each receptor grid was centred on the point source. Point sources were modelled using emission release characteristics from the PCM stack parameters database (described in Section 4.3.1). The NAEI emissions for point sources for 2020 were scaled in order to provide values for 2021 as described in Section 3.

Contributions from PM point sources with less than 200 tonnes per annum release and for which emission characteristics were not known were modelled using the 'small points' model originally described by (Stedman *et al.*, 2005) and summarised in Appendix 3 – Small point source model. This model consists of separate 'in-square' and 'out-of-square' components, in which concentrations are estimated using dispersion kernels, which have been calculated by using ADMS to model the dispersion of unit emissions from a central source to a grid of receptors at a spatial resolution of 1 km x 1 km squares. In line with the method applied for the large point sources the NAEI 2020 emissions for small point sources of PM have been scaled to 2021 using the same source sector specific projection factors applied to the large point sources.

The NAEI 2020 includes point source emissions estimates derived from carbon emissions data reported under the EU-Emissions Trading Scheme (ETS), most recently described in Tsagatakis *et al.* (2022). These point sources are referred to as ETS points in this report. These derived air quality pollutant emissions are particularly uncertain and therefore in previous assessments (e.g. Brookes *et al.* (2017)) emissions were capped at reporting thresholds and treated as small point sources. For the 2016 assessment (Brookes *et al.*, 2019a) the NAEI recommended treating the ETS points that have emissions greater than the large points modelling threshold as large points and not to apply a cap (Personal communication from Ben Pearson, 2022). The 2021 assessment continues this approach. Thus, based on the criteria for the treatment of large point sources described above, ETS point sources were modelled as an additional set of large point sources (using the approach described above). ETS points that were not classified as large point sources were modelled using the PM₁₀ small points approach described above.

6.3.4 Contributions from distant sources of primary particles

Contributions from long-range transport of primary particles on a 20 km x 20 km grid have been estimated using the TRACK receptor oriented, Lagrangian statistical model (Lee *et al.*, 2000). Emissions of primary PM₁₀ were taken from the NAEI for UK sources and from EMEP (WebDab data, <http://www.ceip.at/>) for sources in the rest of Europe. Primary PM₁₀ was modelled as an inert tracer. All sources within 10 km of the receptor point were excluded from the TRACK model to allow the area source model and the point source model to be nested within this long-range transport model without duplicating source contributions. Activity scaling factors were applied to calculate emission values applicable to 2021 from 2020 estimates for the UK and from 2019 estimates for the rest of Europe as described in Section 3.

6.3.5 Iron and calcium rich dusts

6.3.5.1 Introduction

The NAEI does not explicitly include estimates of the emissions of iron or calcium rich dusts. Various process-based or more empirically based methods have therefore been applied to estimate the contribution of these dusts to ambient PM₁₀ concentrations across the UK for sources not included in the NAEI.

The contributions have been split into three categories:

- Regional calcium rich dusts from re-suspension of soils
- Regional iron rich dusts from re-suspension
- Iron rich dusts from re-suspension due to vehicle activity

A method for estimating the mass of iron (Fe) and calcium (Ca) rich dusts was included in the modelling method for PM₁₀ for the first time in 2006. The PCM models were revised for 2008 to incorporate a more process-based modelling approach for regional calcium rich dusts from re-suspension of soils and iron rich dusts from re-suspension due to vehicle activity. The revised models

developed from those proposed by (Abbott, 2008) were also used for this 2021 assessment. The method for regional iron rich dusts remains largely unchanged and is based on a more empirical approach.

The starting point for the assessment of iron and calcium rich dusts is the measurements of a range of PM components including Fe and Ca reported by (Harrison and Yin, 2006) for three monitoring sites in the Birmingham area. Measurements were made at an urban background site (BCCS) from May 2004 to May 2005, an urban roadside site (BROS) from May 2005 to November 2005 and at a rural site about 20 km from the city (CPSS) from November 2005 to May 2006. Measurements were not made at the different sites simultaneously, but the measurement periods were sufficiently long that they can be used to provide reasonable estimates of the urban and roadside increments of various PM components. The measurement data for Fe and Ca are summarised in Table 6.3.

Table 6.3 - Measured concentration of iron and calcium and derived estimates of iron and calcium rich dusts ($\mu\text{g m}^{-3}$)

	CPSS (rural)	BCCS (urban)	Conversion factor	Rural x factor	Urban increment x factor
Fe fine	0.06	0.10	9.0	0.54	0.36
Fe coarse	0.14	0.24	9.0	1.26	0.89
Ca fine	0.03	0.09	4.3	0.13	0.26
Ca coarse	0.12	0.30	4.3	0.52	0.77

Table 6.3 also includes the conversion factors suggested by Harrison et al. (2006) for use within their pragmatic mass closure model. This factor converts the mass of elemental Fe to iron related dusts and the mass of elemental Ca to calcium related dusts. The urban increment in the table has been calculated by subtracting the data for CPSS from that for the urban BCCS site. It is clear that there is an urban increment for both fine and coarse iron and calcium rich dusts. Measurement data for the BROS roadside site indicates that there is a roadside increment on top of the urban increment for Fe but not for Ca. Thus, it is reasonable to assume that the urban increment for iron rich dusts is associated with emissions generated by road traffic but that the urban increment for calcium rich dusts is associated with urban emissions that are not related to traffic activity.

6.3.5.2 Regional calcium rich dusts

The regional concentration of Ca rich dusts was assumed to be a constant value across the UK in the 2006 and 2007 assessments (Kent and Stedman, 2007; Grice *et al.*, 2009). Abbott (2008) developed a method to estimate the ambient concentration of Ca rich PM₁₀ dusts resulting from the re-suspension of soils in rural areas. The starting points for this method are the proportion of bare soil, root crops and cereal crops in 1 km x 1 km grid squares across the UK within the Land Cover Map 2000 (2009). The concentration of Ca rich dusts cannot be calculated using the standard approach of using an estimate of the annual emissions and an air dispersion model. This is because the rate of re-suspension and the atmospheric dispersion of these emissions are both dependant on the meteorological conditions. The emission rate will be higher when the wind is stronger, but the dispersion of these emissions will also be more efficient under these conditions.

The method presented by Abbott (2008) makes use of combined emission and dispersion kernels for cereal and root crop fields and for bare soils. Concentrations were calculated for each hour of the year based on hourly sequential meteorological data from twelve sites throughout the UK for 1999. This year was selected because the data were readily available.

The method of Abbott (2008) has been adapted for use within the PCM models by using an inverse distance weighted average of the results from the different kernels for each receptor location. This revised method avoids the discontinuities caused by the use of a simpler nearest meteorological site to the receptor method used in the original work.

Figure 6.6a shows the results for regional Ca rich dusts. The highest concentrations are predicted to be in eastern areas where bare soils, root and arable crops are more common and there is less rainfall. A maximum value for this component has been set as $5 \mu\text{g m}^{-3}$ within the map. This value has been chosen as an estimate of the maximum likely concentration for a grid square average based on a comparison of this map with available PM₁₀ measurements in the locations with the highest predicted contributions.

6.3.5.3 Urban calcium rich dusts

Prior to 2016 an empirical method was used to estimate the urban increment for Ca rich dusts (Brookes *et al.*, 2017). The NAEI for 2020 that has been used for the 2021 air quality assessment modelling includes a revised method for estimating emissions of PM from construction, first introduced in the NAEI for 2016, that results in an increase in the estimate of emissions from this source. The emissions estimates for this source have been multiplied by a factor of 0.6667 in order to achieve mass closure and provide a consistent calibration of the models for PM₁₀ and PM_{2.5}. This revision means that urban calcium rich dusts are now accounted for within the dispersion modelling and a separate empirically modelled contribution from re-suspension of soils due to urban activity is no longer required.

6.3.5.4 Regional iron rich dusts

A constant value for the regional contribution to Fe rich dusts of 0.5 $\mu\text{g m}^{-3}$ has been applied across the UK. This residual value has been chosen to provide the best fit to the measurements from the Birmingham study (Harrison and Yin, 2006) and available urban background particulate Fe measurements once the estimated contribution from re-suspension due to vehicle movements has been taken into account. Figure 6.6b shows this constant contribution across the UK.

6.3.5.5 Iron rich dusts from re-suspension associated with vehicle movements

The assessments for 2006 and 2007 used an empirical method for the Fe rich dusts associated with re-suspension from vehicle movements based on the use of vehicle km statistics for 1 km x 1 km squares (Grice *et al.*, 2009). Abbott (2008) developed a more process-based approach to estimating this contribution, which takes vehicle km statistics for heavy-duty vehicles (heavy good vehicles and buses) as its starting point. The re-suspension contribution associated with light duty vehicles is expected to be minor compared with that from heavy duty vehicles. These estimates are likely to be subject to greater uncertainty than the estimates for re-suspension from soils because there is little information on the availability of material on road surfaces to be re-suspended.

Abbott (2008) calculated two sets of combined emission and dispersion kernels for each of the 12 meteorological stations for 1999: one to represent rural conditions and one to represent urban conditions. The estimated re-suspension rate was considerably higher for rural conditions due to the higher speeds assumed. These two sets of kernels were then used to calculate the contribution to PM₁₀ concentrations according to the proportion of urban and rural land cover in each 1 km x 1 km grid square. A detailed examination of the results from this assessment has shown that the concentrations in urban areas were largely driven by the small proportion of rural land cover in these urban areas. The urban kernels have therefore been chosen to apply to all roads within the PCM model.

Figure 6.6c shows the results for Fe rich dusts from vehicle movements. The highest concentrations are associated with the roads with the highest flows of heavy-duty vehicles. A maximum value for this component has been set as 2.5 $\mu\text{g m}^{-3}$ within the map. This value has been chosen as an estimate of the maximum likely concentration for a grid square average based on a comparison of this map with available PM₁₀ measurements in the locations with the highest predicted contributions.

An indication that the method is providing reasonable estimates the total of Fe rich dusts is provided by Figure 6.7, which shows a comparison of modelled annual mean Fe (the sum of regional and vehicle related Fe) with ambient Fe measurements at non-industrial and non-roadsite sites for 2021 from the national metals monitoring network. The modelled estimates are clearly of the correct magnitude and provide a reasonable description of the rural to urban gradients.

Figure 6.6**a) Contribution to PM₁₀ from regional Ca rich dusts associated with re-suspension from soils ($\mu\text{g m}^{-3}$)****b) Contribution to PM₁₀ from regional Fe rich dusts ($\mu\text{g m}^{-3}$)****c) Contribution to PM₁₀ from Fe rich dusts associated with vehicle movements ($\mu\text{g m}^{-3}$)**

Figure 6.7 - Comparison of modelled and measured annual mean elemental Fe concentrations 2021 ($\mu\text{g m}^{-3}$)

6.3.5.6 Application to the mapping of heavy metal concentrations

Abbott (2008) also suggested a method for estimating the contributions to the ambient concentrations of heavy metals from soil and vehicle related re-suspension processes. Section 11.3 on the modelling of heavy metal concentrations describe how the maps of PM mass from rural re-suspension of soils and re-suspension associated with vehicle movements have been used to estimate the contributions to the ambient concentration of heavy metals using a combination of information on the heavy metal content of soils and enhancement factors.

6.3.6 Sea salt

The contribution to ambient PM from sea salt has been derived directly from measurements of particulate chloride from sites within the UKEAP AGANet for 2021. Data from a network of 26 rural sites were interpolated using inverse distance weighting onto a 5 km x 5 km grid. A scaling factor of 1.648 was applied to convert elemental chloride mass to sodium chloride mass. 73% of the sea salt mass was assumed to be in the coarse fraction and 27% in the fine fraction. This split was derived from measurement data presented by (Airborne Particles Expert Group (APEG), 1999) and Harrison and Yin (2006).

The use of chloride is potentially subject to both positive and negative artefacts. Sea salt is not the only source of particulate chloride in the atmosphere. HCl is emitted from coal burning but reductions in coal use and flue gas abatement are likely to have reduced atmospheric HCl and ammonium chloride concentrations considerably. There will also be loss of chloride from marine aerosol due to reactions with nitric acid. The resulting sodium nitrate PM has been considered to be of anthropogenic origin and the contribution to PM mass from this sodium nitrate is explicitly included in the modelled concentrations presented. If sodium were used as the marker for sea salt rather than chloride, then this sodium nitrate would tend to be included in the natural component.

In addition to selecting chloride as the marker for sea salt, the analysis was simplified by assuming that the sea salt consists of sodium chloride only. Thus, the measured chloride concentration has been scaled by a factor of 1.648. An alternative approach would be to scale by 1.809 to take account of the full composition of sea salt. The composition of sea salt is dominated by chloride and sodium. Other components contributing more than 1% by mass are sulphate, magnesium, calcium and potassium. Sulphate is already explicitly included in the modelled concentrations and a sea salt correction has not been applied to the measured concentrations used in the PCM model. Adding a further sea salt sulphate component would lead to double counting. The other components (magnesium, calcium and potassium) have, in effect, been treated as sodium by the use of a scaling

factor of 1.648. The ratio of (chloride + sodium) to chloride in sea salt is 1.552, while the ratio of (chloride + sodium + magnesium + calcium + potassium) to chloride is 1.658. Thus, the simplification of sea salt as pure sodium chloride has not had a large impact on the total mass assumed apart from the contribution from sea salt sulphate, which, as a simplification, has been included with the rest of the sulphate as anthropogenic.

6.3.7 Contributions from area sources

Figure 6.8 shows the calibration of the area source model. The modelling method makes use of an ADMS derived dispersion kernel to calculate the contribution to ambient concentrations at a central receptor location from area source emissions within a 33 km x 33 km square surrounding each receptor. Hourly sequential meteorological data from WRF in 2021 was used to construct the dispersion kernels, as described in Appendix 5 – Dispersion kernels for the area source model. A total of 46 background monitoring sites within the national network had sufficient data capture for PM₁₀ and PM_{2.5} in 2021 to be used to calibrate the model. Only sites with valid data for PM₁₀ and PM_{2.5} have been used to calibrate the PM₁₀ and PM_{2.5} models, as described in Section 6.1.

Revised methods introduced in the 2011 assessment (Brookes *et al.*, 2012) for modelling the contributions to PM₁₀ from SNAP 2 (domestic and non-domestic combustion) and SNAP 3 (combustion in industry) area sources were used and have been described in Section 4.3.5.

The methods used to estimate the spatial distribution of emissions from domestic wood combustion were revised for the NAEI 2015 to incorporate new information from a survey of domestic wood use (BEIS, 2016). The revised spatial distribution places a larger proportion of these emissions in large urban areas than in previous assessments. The activity estimates used to derive the estimates of emissions from domestic wood combustion have been revised downwards, resulting in a lower estimate of emissions in the NAEI 2020 than in the NAEI 2019. The larger estimate of domestic emissions in the NAEI 2019 provided a better agreement of the dispersion model results with ambient measurements for PM₁₀ and PM_{2.5} than the lower estimates from the NAEI 2020. A combination of the revised spatial distribution from the NAEI 2020 and the application of a scaling factor of 2.0 to the domestic combustion emissions total was found to provide the best agreement with measurements and calibration coefficients for PM₁₀ and PM_{2.5} close to unity.

The NAEI for 2020 that has been used for the 2021 air quality assessment modelling includes a method for estimating emissions of PM from construction that was first introduced in the NAEI for 2016, which has resulted in an increase in the estimate of emissions from this source. The emissions estimates for this source have been multiplied by a factor of 0.5 in order to achieve mass closure and provide a consistent calibration of the models for PM₁₀ and PM_{2.5}. This revision means that urban calcium rich dusts are now accounted for within the dispersion modelling and a separate empirically modelled contribution from re-suspension of soils due to urban activity is no longer required.

As part of the calibration process emission caps have been applied to certain sectors; this is because the use of surrogate statistics for mapping area source emissions sometimes results in unrealistically large concentrations in some grid squares for a given sector. The emission caps applied are given in Table 6.4.

With the exception of area sources associated with SNAP sector 3 (combustion in industry), the area source model has been calibrated using ambient PM monitoring data from the UK national networks. The modelled large point and small point source, SIA, SOA, iron and calcium rich dust, long range transport primary PM, sea salt and the residual concentrations have been subtracted from the measured annual mean PM concentration at background sites and compared with the modelled area source contribution to annual mean PM concentration. A residual concentration of zero was found to provide the best fit to the monitoring data for both PM₁₀ and PM_{2.5} in 2021.

The modelled area source contribution (excluding SNAP 3) was multiplied by the relevant empirical coefficient to calculate the calibrated area source contribution for each grid square in the country. The area source contribution was then added to the contributions from SNAP 3 area sources, secondary organic and inorganic particles, from small and large point sources, from regional primary particles, from sea salt, from calcium and iron rich dusts and the residual, resulting in a map of background annual mean gravimetric PM₁₀ concentrations.

Figure 6.8 - Calibration of PM₁₀ area source model 2021 ($\mu\text{g m}^{-3}$, gravimetric)**Table 6.4 - Emission caps applied to PM₁₀ sector grids**

SNAP code	Description	Cap applied (t/a/km ²)
SNAP 8 (Other Transport & mobile machinery)	Industrial off-road mobile machinery_Gas oil	3
SNAP 4 (Production process)	Stockpiles	15

6.3.8 Roadside concentrations

The modelled annual mean concentration of PM₁₀ at a roadside location is made up of two parts: the background concentration (as described above) and a roadside increment:

$$\text{roadside PM}_{10} \text{ concentration} = \text{background PM}_{10} \text{ concentration} + \text{PM}_{10} \text{ roadside increment.}$$

The NAEI has provided estimates of PM₁₀ emissions for major road links in the UK for 2021 (Churchill *et al.*, 2022) as described in Section 3. The roadside increment model for PM₁₀ has been calibrated using data from monitoring sites with valid data for both PM₁₀ and PM_{2.5}. The PCM Roads Kernel Model (PCM-RKM) described in Appendix 8 – The PCM Roads Kernel Model has been used to calculate the roadside increment. The PCM-RKM is based upon dispersion kernels generated by the ADMS-Roads dispersion model (v5.0) and represents a more process-based approach than the previous empirical method. It provides a more robust assessment, whilst retaining the link with measurement data provided using AURN measurement data to calibrate this component of the model. Figure 6.9 shows the calibration of this model at roadside monitoring sites. Roadside concentrations for urban major road links (A-roads and motorways) only are reported and included in this report.

Figure 6.9 - Calibration of PM₁₀ PCM-RKM model 2021 ($\mu\text{g m}^{-3}$, gravimetric)

6.4 Results

6.4.1 Verification of mapped values

Figure 6.10 and Figure 6.11 show comparisons of modelled and measured annual mean PM₁₀ concentration at background and roadside monitoring site locations. Lines representing $y = x - 50\%$ and $y = x + 50\%$ are also shown because 50% is the AQSR data quality objective for modelled annual mean PM₁₀ concentrations – see Section 1.5. Summary statistics for the comparison between modelled and measured PM₁₀ concentrations are presented in Table 6.5 and Table 6.6.

There are a number of different categories of monitoring sites within these tables and graphs. This is because there are some sites in the national network at which only PM₁₀ or PM_{2.5} are measured, but not both. TEOM PM₁₀ data adjusted using the VCM model (<http://www.volatile-correction-model.info/>), are available for some verification sites.

The agreement between the measurement data and the modelled values is generally good.

6.4.2 PM₁₀ source apportionment at monitoring sites

Figure 6.12 and Figure 6.13 show the modelled annual mean PM₁₀ source apportionment for 2021 at national network background and roadside monitoring sites respectively. The measured concentration at each site is also shown for reference.

At background locations, the contributions from non-emissions inventory sources (i.e. regional background sources and urban dusts), which are shown in grey on the figures, dominate with a particularly large contribution from secondary inorganic aerosols. The smaller contribution from urban background emissions sources, shown in colour on the figures, is dominated in most locations by domestic, traffic (exhaust emissions, brake and tyre wear and road abrasion) and industry.

At roadside locations the source apportionment follows a very similar pattern to background locations, except that there is an extra local road traffic component composed of local exhaust emissions and local brake and tyre wear and local road abrasion emissions. Depending on the magnitude of the local traffic emissions, local traffic emissions can contribute up to about $6 \mu\text{g m}^{-3}$ of PM₁₀ at the roadside monitoring sites.

Figure 6.12 - Annual mean PM₁₀ source apportionment at background national network monitoring sites in 2021

Figure 6.13 - Annual mean PM₁₀ source apportionment at national network roadside monitoring sites in 2021

6.5 Subtraction of sea salt component

6.5.1 Introduction

The AQSR requires attribution exceedances of limit values due to natural sources when reporting the results of air quality assessments when these occur. The definition of natural sources in the AQSR includes sea spray. An assessment of concentrations with the contribution from natural sources subtracted is provided in e-Reporting Data flow G published on UK-Air (*UK-Air*, 2022) for locations with measured or modelled exceedances of the limit values. Where exceedances are attributed to natural sources, subtraction is a requirement of the AQSR.

6.5.2 Map of annual mean sea salt PM₁₀

The method used to estimate the sea salt contribution to annual mean PM₁₀ concentrations across the UK has been described in Section 6.3.6. The map of annual mean sea salt PM₁₀ can be used to subtract this contribution directly from measured or modelled annual mean concentrations. The uncertainties associated with estimating the sea salt contribution to annual mean PM₁₀ from measurements of particulate chloride have been discussed in Section 6.3.6. It is recognised that the interpolated map of sea salt concentrations will not capture the steep gradients in sea salt concentration very close to the coast. Thus, the analysis presented may underestimate the sea salt contribution to exceedances in coastal areas.

6.5.3 Method for the 24-hour limit value

A method has also been developed to estimate the contribution from sea salt to exceedances of the 24-hour limit value for PM₁₀ of no more than 35 days with concentration greater than 50 µg m⁻³. This method has been described in detail by (Defra, 2009). This method makes use of the relationship between the number of days with concentrations greater than 50 µg m⁻³ and annual mean concentrations described by (Stedman, Bush, *et al.*, 2001). There is some scatter around the best-fit line of the relationship shown in Figure 6.4. Using the best-fit line relationship within the annual method for subtracting sea salt has been considered appropriate since this should give the best central estimate of the sea salt contribution.

An estimate of the number of days with a PM₁₀ concentration greater than 50 µg m⁻³ associated with the contribution to annual mean concentration from sea salt has been calculated by applying the relationship of (Stedman, Bush, *et al.*, 2001) in the vicinity of the limit value. This has been done by calculating the difference between the number of days corresponding to 31.5 µg m⁻³ minus half the sea salt concentration and the number of days corresponding to 31.5 µg m⁻³ plus half the sea salt concentration.

Daily chloride measurements are available for two sites in the south east of the UK. These measurements can be used to calculate a daily sea salt subtraction for PM₁₀ monitoring data. This method is not applicable to model results and will be less reliable for sites not in the south east of the UK. For these reasons the method based on annual mean sea salt concentrations has been used across the UK as described above. (Defra, 2009) have provided a comparison of the annual and daily methods for the years 2005, 2006 and 2007 which shows that the agreement between the methods is reasonably good.

6.5.4 Results

There were no reported exceedances of the 24-hour or annual mean limit values for PM₁₀ in 2021.

7 PM_{2.5}

7.1 Introduction

7.1.1 Limit and Target values

The AQSR (*legislation.gov.uk*, 2010) includes a target value (TV) for annual mean PM_{2.5} which came into force from 01/01/2010. This target value is:

- An annual mean concentration of 25 µg m⁻³.

A limit value was also set for ambient PM_{2.5} concentrations and came into force on 01/01/2015:

- An annual mean concentration of 25 µg m⁻³.

A revised limit value (*legislation.gov.uk*, 2020) came into force on 01/01/2020 of:

- An annual mean concentration of 20 µg m⁻³.

There were no measured or modelled exceedances of the annual mean target value or limit value for PM_{2.5} in 2021.

An exposure reduction target and an exposure concentration obligation have also been set for PM_{2.5}.

Results of the assessment in terms of comparisons of the modelled concentrations with the annual mean limit and target values for PM_{2.5} have been reported in e-Reporting Data flow G published on UK-Air (*UK-Air*, 2022).

7.1.2 Annual mean model

Maps of annual mean PM_{2.5} in 2021 at background and roadside locations are shown in Figure 7.1 and Figure 7.2.

Full details of the models used to calculate concentrations of PM₁₀ and PM_{2.5} are provided in Section 6. The maps have been calibrated using measurements within the national network for which co-located PM₁₀ measurements are also available. The models for PM₁₀ and PM_{2.5} are designed to be fully consistent, with each component either derived from emission estimates for PM₁₀ or PM_{2.5}, or the contributions to the fine and coarse particle size fractions are estimated separately. This enables us to carry out an additional sense check that the calibration parameters for the two pollutants are reasonably consistent. Measurements from national network sites without collocated PM₁₀ instruments have been used as an additional verification dataset.

The concentrations of many of the modelled components have been estimated separately for the fine and coarse fraction. This enables a consistent method to be adopted for estimation of PM₁₀ (the sum of the fine and coarse fractions) and PM_{2.5} (fine fractions only). The mass fractions of each component assigned to PM_{2.5} are listed in Section 7.3.1. The component pieces are then aggregated to a single 1 km x 1 km background PM_{2.5} grid. An additional roadside increment is added for roadside locations.

The results from the annual mean model can be directly compared with the annual mean target and limit values in order to carry out the air quality assessment.

Heading	Component	Details
Calibration	Model calibrated?	Yes
	Number of background stations in calibration	46 (stations with both PM ₁₀ and PM _{2.5})
	Number of traffic stations in calibration	15 (stations with both PM ₁₀ and PM _{2.5})
Pollutant specific	Secondary inorganic aerosol	Interpolated from SO ₄ , NO ₃ and NH ₄ measurements at 27 rural stations, scaling factors applied for size fraction, bound water and counterions
	Secondary organic aerosol	Results from the NAME model for 2008
	Regional primary particles	Calculated using the TRACK receptor oriented, Lagrangian statistical model
	Regional calcium rich dusts from re-suspension of soils	Modelled using information on land cover (bare soil, root and cereal crops) and dispersion kernel incorporating emissions and dispersion processes
	Regional iron rich dusts from re-suspension	Assigned a constant value of zero
	Iron rich dusts from re-suspension due to vehicle activity	Modelled using information on vehicle movements on major roads (HDV) and dispersion kernel incorporating emissions and dispersion processes
	Sea Salt	Interpolated measurements of Cl, scaling factor applied for sea water composition
	Residual	A value assigned based on best fit to PM ₁₀ and PM _{2.5} measurements: zero, no residual required

7.1.4 Chapter Structure

This chapter describes modelling work carried out for 2021 to assess compliance with the PM_{2.5} limit and target values described above. Emission estimates for primary PM are described in Section 7.2, Section 7.3 describes the PM_{2.5} modelling methods. The modelling results in terms of verification and source apportionment are presented in Section 7.4. The methods used to subtract the contribution from natural sources (sea salt) and the results of this subtraction are presented in Section 7.5. The method used to calculate the average exposure indicator (AEI) for annual mean PM_{2.5} and an assessment of compliance with the exposure concentration obligation is presented in Section 7.6.

7.2 PM_{2.5} emissions

Estimates of the emissions of primary PM from the UK National Atmospheric Emission Inventory 2020 (NAEI 2020) have been used in this study (Churchill *et al.*, 2022). Emissions projections have been provided by the NAEI (Personal communication from Ben Pearson, 2022) based on BEIS EEP 2021 energy and emissions projections (BEIS, 2022). The methods used to calculate projections 2020 to 2021 from taking the impact of the reduced activity levels in 2020 and 2021 have been calculated as described in Section 3.

Figure 7.4 shows UK total PM_{2.5} emissions for 2021, with the coding described in Table 4.2. The figure shows that PM_{2.5} emissions in 2021 include contributions from a wide range of different source sectors. The figure shows that PM₁₀ emissions in 2021 are dominated by two main sources:

- SNAP 2: Domestic combustion
- SNAP 3: Industrial combustion.

The methods used to calculate ambient concentrations from the estimates of primary PM emissions are described below for point, area, road link and regional sources.

Figure 7.4 - Total UK PM_{2.5} emissions for 2021 by SNAP code scaled using Covid factors from NAEI 2020

7.3 PM_{2.5} modelling

7.3.1 PM_{2.5} mass fractions

The proportions of the PM mass for each component assigned to the PM_{2.5} fraction within the PCM models are listed in Table 7.2. The proportions for secondary inorganic aerosols have been derived as described in Section 6.3.1. The proportions for local point and area sources are based on the NAEI emission inventories for PM_{2.5} and PM₁₀ (Churchill *et al.*, 2022). The NAEI PM_{2.5} emission inventory has been derived from the PM₁₀ emission inventory by the application of estimates of the mass fraction represented by PM_{2.5} for different sources and fuels. Overall, the UK total mass emissions for PM_{2.5} for 2020 were about 58% of the value for PM₁₀. The proportions for calcium and iron rich dusts have been derived with reference to the monitoring data presented in Section 6.3.5 and to provide good fit to the available co-located PM_{2.5} and PM₁₀ measurements. The proportions for calcium and iron rich dusts were updated for 2017, 2018, 2019, 2020 and 2021 in order to account for the revised method for measurement of SIA (Tang *et al.*, 2015) and revised spatial distribution of emissions from domestic wood combustion and to provide a consistent calibration for PM₁₀ and PM_{2.5}. The proportion for sea salt has been derived as described in Section 6.3.6. The proportion for secondary organic aerosol, has been set at 1.0 for PM_{2.5} so as to provide best fit to the available measurements.

Table 7.2 - The proportion of PM mass assigned to the PM_{2.5} and PM_{2.5-10} size fractions

Component	Fine fraction (PM _{2.5})	Coarse fraction (PM _{2.5-10})
SO ₄	0.94	0.06
NO ₃	0.556 (fine mode), 0.222 (coarse mode)	- (fine mode), 0.222 (coarse mode)
NH ₄	0.97	0.03
SOA	1.00	-
Large point sources of primary particles	PM _{2.5} emission inventory*	PM ₁₀ emission inventory
Small point sources of primary particles	PM _{2.5} emission inventory*	PM ₁₀ emission inventory
Regional primary particles	PM _{2.5} emission inventory*	PM ₁₀ emission inventory
Area sources of primary particles	PM _{2.5} emission inventory*	PM ₁₀ emission inventory
Rural calcium rich dusts from re-suspension of soils	0.1	0.9
Regional iron rich dusts from re-suspension	0	1.0
Iron rich dusts from re-suspension due to vehicle activity	0.1	0.9
Sea salt	0.27	0.73
Residual	n/a	n/a

* The NAEI PM_{2.5} emission inventory has been derived from the PM₁₀ emission inventory by the application of estimates of the mass fraction represented by PM_{2.5} for different sources and fuels.

7.3.2 Contributions from large and small point sources

The contributions from large and small point sources have been calculated in the same way as for the PM₁₀ model described in Section 6.3.3.

7.3.3 Contributions from area sources

Figure 7.5 shows the calibration of the area source model for PM_{2.5}. The calibration coefficient for PM_{2.5} is quite similar to the calibration coefficient for PM₁₀. The small difference is considered to be well within the uncertainty of the PM₁₀ and PM_{2.5} measurements and the PM_{2.5} mass fractions within the emission inventory. A reasonably good agreement between the calibration coefficients for area sources is one of the criteria for the choice of mass fraction parameters for PM_{2.5} within the PCM model.

As part of the calibration process emission caps have been applied to certain sectors; this is because the use of surrogate statistics for mapping area source emissions sometimes results in unrealistically large concentrations in some grid squares for a given sector. The emission caps applied are given in Table 7.3.

Figure 7.5 - Calibration of PM_{2.5} area source model 2021 ($\mu\text{g m}^{-3}$, gravimetric)**Table 7.3 - Emission caps applied to PM_{2.5} sector grids**

SNAP code	Description	Cap applied (t/a/km^2)
SNAP 8 (Industrial off-road mobile machinery)	Industrial off-road mobile machinery_Gas oil	2.3

SNAP 4 (Production process)	Stockpiles	9

7.3.4 Roadside concentrations

Figure 7.6 shows the calibration of the roadside increment model for annual mean $PM_{2.5}$ concentrations.

Figure 7.6 - Calibration of $PM_{2.5}$ roadside increment model 2021 ($\mu g\ m^{-3}$, gravimetric)

7.4 Results

7.4.1 Verification of mapped concentrations

Figure 7.7 and Figure 7.8 show comparisons of modelled and measured annual mean $PM_{2.5}$ concentrations in 2021 at background and roadside monitoring site locations. Lines representing $y = x - 50\%$ and $y = x + 50\%$ are also shown because 50% is the AQSR data quality objective for modelled annual mean $PM_{2.5}$ concentrations – see Section 1.5.

Summary statistics for the comparison between modelled and measured $PM_{2.5}$ concentrations are presented in Table 7.4 and Table 7.5.

There are several different categories of monitoring sites within these tables and graphs. This is because there are some sites in the national network at which only PM_{10} or $PM_{2.5}$, but not both are measured.

The agreement between the measurement data and the modelled values is generally good.

Figure 7.7 - Verification of background annual mean PM_{2.5} model 2021Figure 7.8 - Verification of roadside annual mean PM_{2.5} model 2021

Table 7.4 - Summary statistics for comparison between gravimetric modelled and measured concentrations of PM_{2.5} at background sites

7.4.2 PM_{2.5} source apportionment at monitoring sites

Figure 7.9 and Figure 7.10 show the modelled annual mean PM_{2.5} source apportionment for 2021 at national network background and roadside monitoring sites respectively. The measured concentration at each site is also shown for reference.

At background locations, the contributions from non-emissions inventory sources (i.e. regional background sources and urban dusts), which are shown in grey on the figures, dominate with a particularly large contribution from secondary inorganic aerosols. The smaller contribution from urban background emissions sources, shown in colour on the figures, are dominated in most locations by domestic, traffic and industry.

At roadside locations the source apportionments follow a very similar pattern to background locations, except that there is an extra local road traffic component composed of local exhaust emissions, local brake and tyre wear emissions and local road abrasion emissions.

Overall regional secondary PM make a proportionally larger contribution to the total mass for PM_{2.5} than for PM₁₀.

Figure 7.9 - Annual mean PM_{2.5} source apportionment at background national network monitoring sites 2021

Figure 7.10 - Annual mean PM_{2.5} source apportionment at roadside national network monitoring sites 2021

7.5 Subtraction of sea salt component

7.5.1 Introduction

The AQSR requires attribution exceedances of limit values due to natural sources when reporting the results of air quality assessments when these occur. The definition of natural sources in this directive includes sea spray. An assessment of concentrations with the contribution from natural sources subtracted is provided in e-Reporting Data flow G published on UK-Air (*UK-Air*, 2022) for locations with measured or modelled exceedances of the limit values. Where exceedances are attributed to natural sources, subtraction is a requirement of the Directive.

7.5.2 Map of annual mean sea salt PM_{2.5}

The method used to estimate the sea salt contribution to annual mean PM_{2.5} concentrations across the UK has been described in Section 6.3.6. The map of annual mean sea salt PM_{2.5} can be used to subtract this contribution directly from measured or modelled annual mean concentrations. The uncertainties associated with estimating the sea salt contribution to annual mean PM_{2.5} from measurements of particulate chloride have been discussed in Section 6.3.6. It is recognised that the interpolated map of sea salt concentrations will not capture the steep gradients in sea salt concentration very close to the coast. Thus, the analysis presented may underestimate the sea salt contribution to exceedances in coastal areas.

7.5.3 Results

There were no measured or modelled exceedances of the annual mean target value, Stage 1 limit value for PM_{2.5} in 2021. Therefore, there was no requirement to subtract the natural contribution.

7.6 Average Exposure Indicator

An exposure reduction target (ERT) and an exposure concentration obligation (ECO) for PM_{2.5} have been set within the AQSR. Both environmental objectives are based on the value calculated for the average exposure indicator (AEI). The AEI is calculated as the three-year average of annual mean measurements at urban background and suburban background monitoring sites (listed in Appendix 7 – Monitoring stations used in PM_{2.5} AEI calculation) across the country.

The AEI for the reference year 2021 has been calculated from measurements made during the years 2019, 2020 and 2021. The method used to calculate the AEI for the 2021 reference year is the same as was used for the previous assessments (Brookes *et al.*, 2012, 2013, 2015, 2016, 2017, 2019b, 2019a, 2020, 2021; Pugsley *et al.*, 2022). An assessment of compliance with the ECO is also presented in this section.

The AEI for the UK has been calculated using the method set out in guidance received for comment from the Commission on 3rd August 2012. This guidance was entitled “Procedures for Determining a National Average Exposure Indicator, for Assessment of a National Exposure Reduction Target, Requirements for Quality Assurance/Quality Control, and Requirements for the Estimation of their Measurement Uncertainties”. The guidance sets out recommended processes but recognises that Member States may adopt other procedures, and it confirms the order of the calculation method for this three-year average. An average is calculated across all of the sites for each year and the three-year average is then calculated from the values calculated for each year. The guidance also proposes a method for weighting the averages for each year according to the data capture achieved.

A total of 41 urban background and suburban background sites were included in the calculation for the 2021 assessment. The calculation is based on the following excerpt from the AQUILA guidance.

$$AEI(p) = \frac{\sum_{i=1}^n (\bar{x}_i d_i)}{\sum_{i=1}^n (d_i)}$$

$$\bar{x}_i = \frac{\sum_{j=1}^k (x_{ij})}{k}$$

Where: d_i is the data capture at the i^{th} station, for all stations where $d_i \geq 75\%$, \bar{x}_i is the annual mean concentration in the year p at station i with the total of n stations, x_{ij} is the daily or hourly average

concentration measured at station i during every valid sampling day or hour j , and k is the number of valid sampling days or hours during the year at that site.

$$AEI = \frac{\sum_p AEI(p)}{3}$$

It is expected that there will have been forced changes in site selection and equipment types between 2010 and 2020 which will impact on the uncertainty of the calculation.

The years 2019, 2020 and 2021 were used for the calculation, with means of 10.0, 7.9 and 7.9 $\mu\text{g m}^{-3}$ respectively.

The mean of these three values (rounded to integer) is 9 $\mu\text{g m}^{-3}$. This is the AEI for the reference year of 2021. This value is compliant with the ECO of 20 $\mu\text{g m}^{-3}$ to be achieved by 2015 set within the AQSR.

The baseline AEI (based upon the years 2009, 2010, 2011) determined the National Exposure Reduction Target (NERT), to be achieved by 2020. With a value of 13 $\mu\text{g m}^{-3}$ as the baseline AEI, the AQSR required the UK to reduce the AEI by 15% from this value of 13 $\mu\text{g m}^{-3}$ in the three-year average for the reference year 2020. This was achieved and the AEI for the reference year of 2021 remains below this value.

8 Benzene

8.1 Introduction

8.1.1 Limit values

A single limit value for ambient benzene concentrations is set out in the Air Quality Directive Standards Regulations (AQSR) (*legislation.gov.uk*, 2010). This limit value has been specified for the protection of human health and came into force on 01/01/2010. The limit value is an annual mean concentration of $5 \mu\text{g m}^{-3}$.

Modelled and measured benzene concentrations for 2021 were below the limit value for all zones.

8.1.2 Annual mean model

Maps of annual mean benzene concentrations at background and roadside locations in 2021 are presented in Figure 8.2 and Figure 8.3 respectively.

Benzene concentrations have been calculated using a similar approach to that adopted for NO_x although a different approach has been adopted for the modelling of fugitive and process emissions from point sources.

8.1.3 Overview of the PCM model for benzene

Figure 8.1 shows a simplified flow diagram of the PCM model for benzene. A summary of the PCM model method, input and assumptions for benzene is presented in Table 8.1.

Figure 8.1 - Flow diagram for PCM benzene model

	Number of traffic stations in calibration	9
Pollutant specific	n/a	n/a

8.1.4 Outline of the annual mean model for benzene

The map of annual mean background benzene concentrations includes contributions from:

- Distant sources (characterised by an estimate of rural background concentration)
- Combustion point sources
- Fugitive and process point sources
- Point sources with emissions estimates for air quality pollutants based on reported carbon emissions (ETS points)
- Local area sources

The area source model has been calibrated using measurements from the national monitoring networks. At locations close to urban roads an additional roadside contribution was added to account for contributions to total benzene from road traffic sources.

8.1.5 Chapter structure

This chapter describes modelling work carried out for 2021 to assess compliance with the benzene annual mean limit value described above. Emission estimates for benzene are described in Section 8.2, Section 8.3 describes the benzene modelling methods, and the modelling results in terms of verification and source apportionment are presented in Section 8.4.

Figure 8.2 - Annual mean background benzene concentration, 2021 ($\mu\text{g m}^{-3}$)

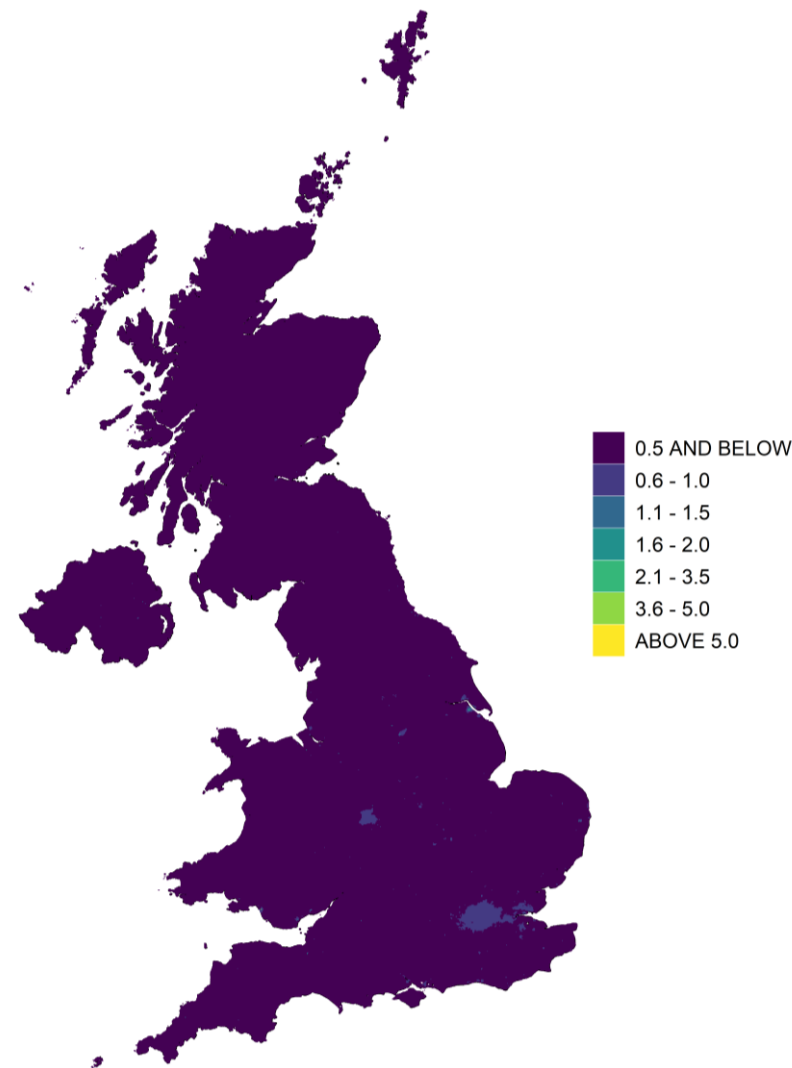

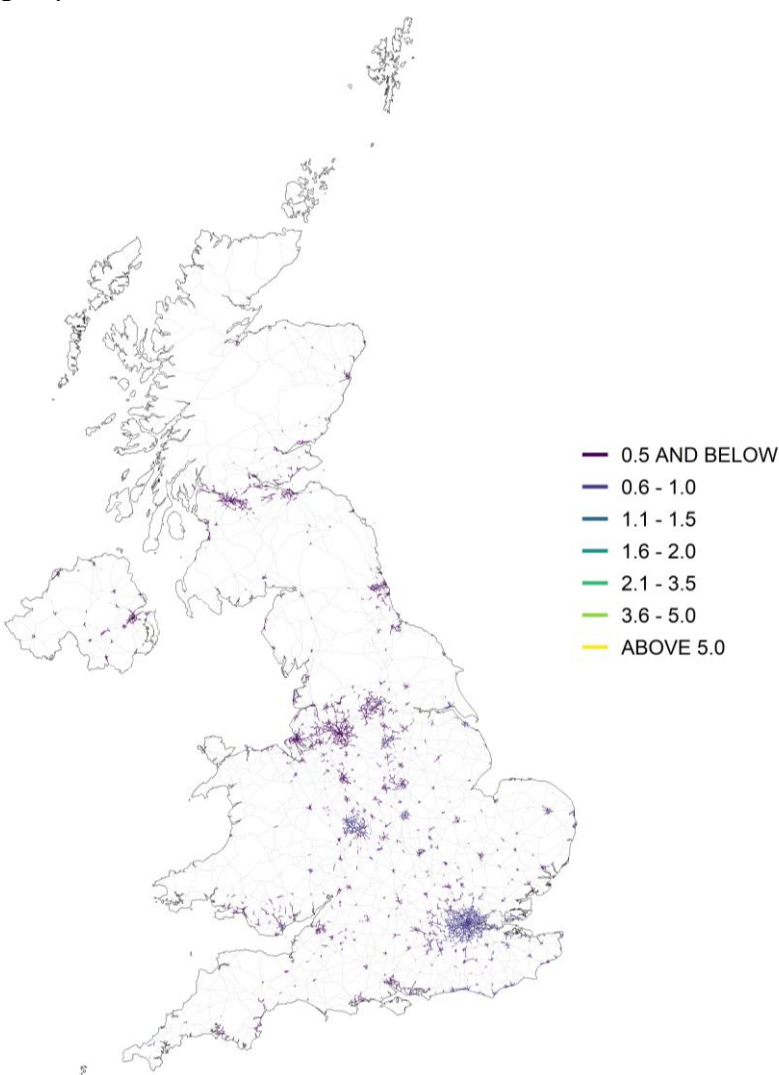

Figure 8.3 - Urban major roads, annual mean roadside benzene concentration, 2021 ($\mu\text{g m}^{-3}$)

8.2 Benzene emissions

Estimates of the emissions of benzene from the UK National Atmospheric Emission Inventory 2020 (NAEI 2020) have been used in this study (Churchill *et al.*, 2022). Emissions projections have been provided by the NAEI (Personal communication from Ben Pearson, 2022) based on BEIS EEP 2021 energy and emissions projections (BEIS, 2022).

Figure 8.4 shows the UK total benzene emissions for 2021, with the coding described in Table 4.2. The emissions include contributions from a variety of source sectors. The figure shows that benzene emissions in 2021 are dominated by one main source, SNAP 2 - domestic combustion.

Figure 8.4 - Total UK benzene emissions for 2021 by SNAP code scaled using Covid factors from NAEI 2020

8.3 Benzene modelling

8.3.1 Contributions from large point sources

Following a similar methodology as for NO_x, benzene point sources in the NAEI 2020 have been classified as large if they fulfil any of the following criteria:

- Annual benzene emissions in the NAEI 2020 are greater than 5 tonnes for any given plant
- Stack parameters are already available for any given plant in the PCM stack parameters database (described in more detail in Section 4.3.1)
- Emissions are not associated with fugitive releases

Contributions to ground level annual mean benzene concentrations from large point sources in the NAEI 2020 were estimated by modelling each source explicitly using the atmospheric dispersion model ADMS 5.2 and sequential meteorological data for 2021 from the WRF numerical weather prediction modelling system, as described in Appendix 4 – WRF meteorology. The WRF model is a next-generation numerical weather prediction system developed by the US National Centre for Atmospheric Science (NCAR) (UCAR, 2020). This method accounts for spatial variation in meteorological parameters across the UK representing local dispersion characteristics within the PCM

output. A total of 5 point sources were modelled as large point sources. Surface roughness varied at both the dispersion and meteorological sites depending on the area type as presented in Table A5.1. Concentrations were calculated for a 99 km x 99 km square composed of a regularly spaced 1 km x 1 km resolution receptor grid. Each receptor grid was centred on the point source. For each large point source information was retrieved from the PCM stack parameters database.

The NAEI emissions for combustion point sources are for the year 2020; however, the year 2021 has been modelled for the assessment. The NAEI emissions for point sources for 2020 were therefore scaled to provide values for 2021 as described in Section 4.3.1.

The NAEI 2020 includes point source emissions estimates derived from carbon emissions data reported under the EU-Emissions Trading Scheme (ETS), most recently described in (Tsagatakis *et al.*, 2022). These point sources are referred to as ETS points in this report. These derived air quality pollutant emissions are particularly uncertain and therefore in previous assessments (e.g. (Brookes *et al.*, 2017)) emissions were capped at reporting thresholds and treated as small point sources. For the 2016, 2017, 2018, 2019 and 2020 assessments (Brookes *et al.*, 2019b, 2019a, 2020, 2021; Pugsley *et al.*, 2022) the NAEI recommended treating the ETS points that have emissions greater than the large points modelling threshold as large points and not to apply a cap (Personal communication from Ben Pearson, 2022). The 2021 assessment continues this approach. Thus, based on the criteria for the treatment of large point sources described above, 30 ETS point sources were modelled as an additional set of large point sources (using the approach described above). ETS points that were not classified as large point sources were modelled using the benzene fugitive and small points approach described next.

8.3.2 Contributions from fugitive and small point sources

In line with the method applied for the large point sources the NAEI 2020 emissions for fugitive and small point sources have been scaled to 2021 using the same source sector specific projection factors applied to the large point sources, described in Section 3.

The contributions to ambient concentrations from fugitive and small point sources were modelled using a small points modelling approach adapted specifically for fugitive and small point sources of benzene. The emissions from these sources are not generally as well characterised in terms of exact location and release parameters as emissions from large combustion related sources. Separate models are used for the concentration in the 1 km x 1 km grid square that includes the source (the 'in-square' concentration) and the concentration in surrounding grid squares (the 'out-square' concentration). The 'out-square' concentration has been estimated using a dispersion kernel similar to the one used for area sources of benzene. Hourly sequential meteorological data from the WRF model in 2021 has been used to construct the dispersion kernels. The 'in square' concentration has been estimated by assuming a volume source of dimensions 200 m x 200 m x 30 m in the centre of the square with the concentration estimated as the average across receptors excluding those inside the central 800 m x 800 m of the 1000 m x 1000 m grid square. These parameters have been chosen to provide the best fit to the range and maximum of available monitoring data in the vicinity of refineries (Grice *et al.*, 2009).

8.3.3 Contributions from rural background concentrations

Regional rural benzene concentrations were estimated from the map of rural NO_x concentration described in Section 4.3.4. The rural NO_x map was scaled using the ratio of averaged measured annual mean benzene and NO_x concentrations at the rural Chilbolton monitoring site across the last five period (2017 to 2021). This resulted in a value of 0.046042 for 2021. This is the method that was followed in 2019 and 2020 (Brookes *et al.*, 2021; Pugsley *et al.*, 2022). However, previous to this an alternative method was followed, where the ratio was based on annual mean benzene and NO_x for the current modelling year only. The method change was implemented to reduce sensitivity of this component to a single year of measurements at a single site. Chilbolton has been the only rural background site in recent years providing sufficient data for both NO_x and benzene, and in 2020 and 2021 the data capture was low at this site. In 2019 benzene measurements were higher than previous years, more consistent with benzene measurements at urban background locations in the network. Therefore this new method was adapted. The use of a five year average ensured that the ratio used was more consistent with previous assessments. This approach will be kept under review to ensure it remains appropriate for the future.

8.3.4 Contributions from area sources

The 2021 area source benzene emissions maps have been calculated from the NAEI 2020 emissions maps following the method applied for NO_x, described in Section 4.3.5. An ADMS derived dispersion kernel has been used to calculate the contribution to ambient concentrations at a central receptor location from the area source emissions (excluding SNAP 3) within a 33 km x 33 km square surrounding each receptor. Hourly sequential meteorological data from WRF in 2021 has been used to construct the dispersion kernels, as described in Appendix 5 – Dispersion kernels for the area source model.

Revised methods introduced in the 2011 assessment (Brookes *et al.*, 2012) for modelling the contributions to benzene from SNAP 2 (domestic and non-domestic combustion) and SNAP 3 (combustion in industry) area sources were used and have been described in Section 4.3.5.

The calibration coefficient for the area source model is derived by linear regression of a corrected measured annual mean background benzene concentration versus the modelled uncalibrated area source contribution. The measurements were derived from one site within the national automatic hydrocarbon network (London Eltham) and 17 non-automatic hydrocarbon sites. The corrected background concentration is derived by subtraction of the modelled contributions from SNAP 3 area sources, point sources and estimated rural benzene from the measured annual mean concentration at automatic and non-automatic pumped tube background monitoring sites. Figure 8.5 shows the calibration of the area source model.

The modelled area source contribution (excluding SNAP 3) was multiplied by the background calibration coefficient to calculate the calibrated area source contribution for each grid square in the country. The SNAP 3 area source contribution, point source contributions and regional rural concentration were then added, resulting in a map of total background annual mean benzene concentrations.

Figure 8.5 - Calibration of area source benzene model, 2021 ($\mu\text{g m}^{-3}$)

8.3.5 Roadside concentrations

Roadside annual mean concentrations of benzene for 2021 have been modelled using a similar method to the NO_x modelling described in Section 4.3.6. The NAEI provides estimates of benzene emissions for major road links in the UK for 2020 (Churchill *et al.*, 2022) and these have been scaled to provide estimates of emissions in 2021. The projections for benzene road transport emissions include the inputs and assumptions summarised in Table 8.1.

The PCM Roads Kernel Model (PCM-RKM) described in Appendix 8 – The PCM Roads Kernel Model has been used to calculate the roadside increment. The PCM-RKM is based upon dispersion kernels generated by the ADMS-Roads dispersion model (v5.0) and represents a more process-based approach than the previous empirical method. It provides a more robust assessment, whilst retaining the link with measurement data provided using measurement data to calibrate this component of the model. Figure 8.6 shows the calibration of this model at roadside monitoring sites. Roadside concentrations for urban major road links (A-roads and motorways) only are reported to the EU and included in this report.

Measurements from one site within the national automatic hydrocarbon network and 8 non-automatic hydrocarbon sites were used to calibrate the roadside model.

Figure 8.6 - Calibration of benzene roadside increment model, 2021 ($\mu\text{g m}^{-3}$)

8.4 Results

8.4.1 Verification of mapped values

Figure 8.7 and Figure 8.8 show comparisons of the modelled and measured annual mean benzene concentrations for background and roadside locations. Lines showing $y = x - 50\%$ and $y = x + 50\%$ are included in these charts (the data quality objective for modelled benzene concentrations specified by the AQSR – see Section 1.5).

One monitoring site that was not included in the calibration are included in Figure 8.7. Summary statistics for the comparison between modelled and measured benzene concentrations are listed in Table 8.2 and Table 8.3.

8.4.2 Benzene source apportionment at monitoring sites

Figure 8.9 and Figure 8.10 show the modelled annual mean benzene source apportionment for 2021 at background and roadside monitoring sites, respectively. The measured concentration at each site is also shown for reference. The regional background is an important component in the source apportionment for the majority of background monitoring sites. Contributions from domestic and industry sources are also important for many sites classified as urban and suburban background. The roadside source apportionment in Figure 8.10 shows that local traffic sources contribute up to $0.1 \mu\text{g m}^{-3}$ of benzene at these roadside sites, with the exception of London Marylebone Road where local traffic sources contribute $0.2 \mu\text{g m}^{-3}$ of benzene.

Figure 8.9 - Annual mean benzene source apportionment at background monitoring sites in 2021 (the area type of each site is shown in parenthesis after its name)

Figure 8.10 - Annual mean benzene source apportionment at roadside monitoring sites in 2021 (the area type of each site is shown in parenthesis after its name)

9 CO

9.1 Introduction

9.1.1 Limit values

A single limit value for ambient CO concentrations is set out in the AQSR (*legislation.gov.uk*, 2010). This limit value has been specified for the protection of human health. The limit value is a maximum daily 8-hour mean concentration of 10 mg m⁻³.

9.1.2 Objective Estimation

The maximum measured daily 8 hour running mean for 2021 are presented in Table 9.1 for all sites. Data capture was greater than 85% at two sites, during 2021. All values are below the lower assessment threshold of 5 mg m⁻³.

Table 9.1 - Maximum daily 8-hour running mean (mg m⁻³) in 2021⁶

EOI code	Site Name	Maximum daily 8-hour running mean (mg m ⁻³)	Data capture (%)
GB0567A	Belfast Centre	0.55	70
GB0580A	Cardiff Centre	0.59	80
GB0839A	Edinburgh St Leonards	0.60	61
GB0584A	Leeds Centre	0.88	94
GB0682A	London Marylebone Road	1.70	84
GB0620A	London N. Kensington	0.99	40
GB0906A	Port Talbot Margam	2.90	99

The AQSR states that objective estimation may be used to assess ambient air quality at levels below the lower assessment threshold. Objective estimation has been used to conclude that concentrations were likely to have been well below the limit value for CO in all zones during 2021. This assessment has been made on the basis of the low measured concentrations and the lack of any expected large increase in future CO emissions illustrated in the following section.

9.1.3 CO emissions

Estimates of the emissions from the UK National Atmospheric Emission Inventory 2020 (NAEI 2020) have been used in this assessment (Churchill *et al.*, 2022). Emissions projections have been provided by the NAEI (Personal communication from Ben Pearson, 2022) based on BEIS EEP 2021 energy and emissions projections (BEIS, 2022). Figure 9.1 shows the UK total CO emissions for 2020 and emissions projections for 2025 and 2030 split by SNAP code, with the coding described in Table 4.2. Values for intermediate years have been interpolated in this figure.

Road transport exhaust emissions continue to decrease to 2020, with relatively small increases in emissions beyond 2020. Emissions from domestic combustion are expected to decline throughout the period. Emissions from off-road mobile machinery are expected to show a small increase. Overall, the changes in emissions shown in Figure 9.1 are relatively small when viewed in the context of the significant decreases in CO emissions from road transport, domestic combustion and combustion point sources (SNAP codes 1-3) from 1990 to 2020 present in the NAEI 2020 (Churchill *et al.*, 2022), which led to a reduction in total UK emissions of CO over this period of 79%.

⁶ Values have been presented to 2 significant figures to illustrate the dynamic range of the data.

Figure 9.1 - Total UK CO emissions for 2020 and emissions projections up to 2030 by SNAP code from NAEI 2020

10 Ozone

10.1 Introduction

10.1.1 Target values and long-term objectives

Two target values (TV) for ambient ozone concentrations are set out in the AQSR ([legislation.gov.uk](https://www.legislation.gov.uk), 2010), these are:

- A maximum daily 8-hour mean concentration of $120 \mu\text{g m}^{-3}$, not to be exceeded on more than 25 days per calendar year averaged over three years
- AOT40⁷ (calculated from 1-hour values) of $18000 \mu\text{g m}^{-3}\cdot\text{h}$ May to July averaged over five years

The TVs have been specified for the protection of human health and the protection of vegetation respectively, both came into force from 01/01/2010.

Two long term objectives (LTO) for ambient ozone concentrations are also set out in the AQSR, these are:

- A maximum daily 8-hour mean concentration of $120 \mu\text{g m}^{-3}$ within a calendar year
- AOT40 (calculated from 1-hour values) of $6000 \mu\text{g m}^{-3}\cdot\text{h}$ May to July

The LTOs have been specified for the protection of human health and the protection of vegetation respectively. The date for compliance with the LTOs has not been defined.

Results of the assessment in terms of comparisons of the modelled concentrations with the TVs and LTOs by zone have been reported in e-Reporting Data flow G published on UK-Air ([UK-Air](https://www.uk-air.org.uk), 2022).

10.1.2 Ozone modelling

An empirical mapping approach has been used for predicting ozone concentrations in 2021; this follows recommendations originally made by (Bush and Targa, 2005) in a study comparing the relative performance of the available techniques for modelling ozone within the UK.

The empirical approach draws upon measurements from the monitoring stations in the AURN during 2021 to produce functions describing ground-level ozone based on interpolated rural measurements of the ozone metrics corrected for local emissions of NO_x . These functions predict ozone levels at a resolution of $1 \text{ km} \times 1 \text{ km}$ and the methods are briefly described in the following sections. Full details can be sourced from the cited references.

The methods used here are based upon those presented by (PORG (UK Photochemical Oxidants Review Group), 1998; NEG-TAP, 2001; Coyle *et al.*, 2002; Murrells *et al.*, 2011). (Murrells *et al.*, 2011) suggested that the observed dependence of the AOT40 metric on altitude, previously attributed to differences in surface deposition and reactions with local NO with altitude, was largely explained by the proximity of monitoring stations to urban areas. The 2021 assessment of the TV and LTO for AOT40, takes on the recommendations of (Murrells *et al.*, 2011) and does not include an altitude correction and thus avoids double counting the NO_x urban decrement.

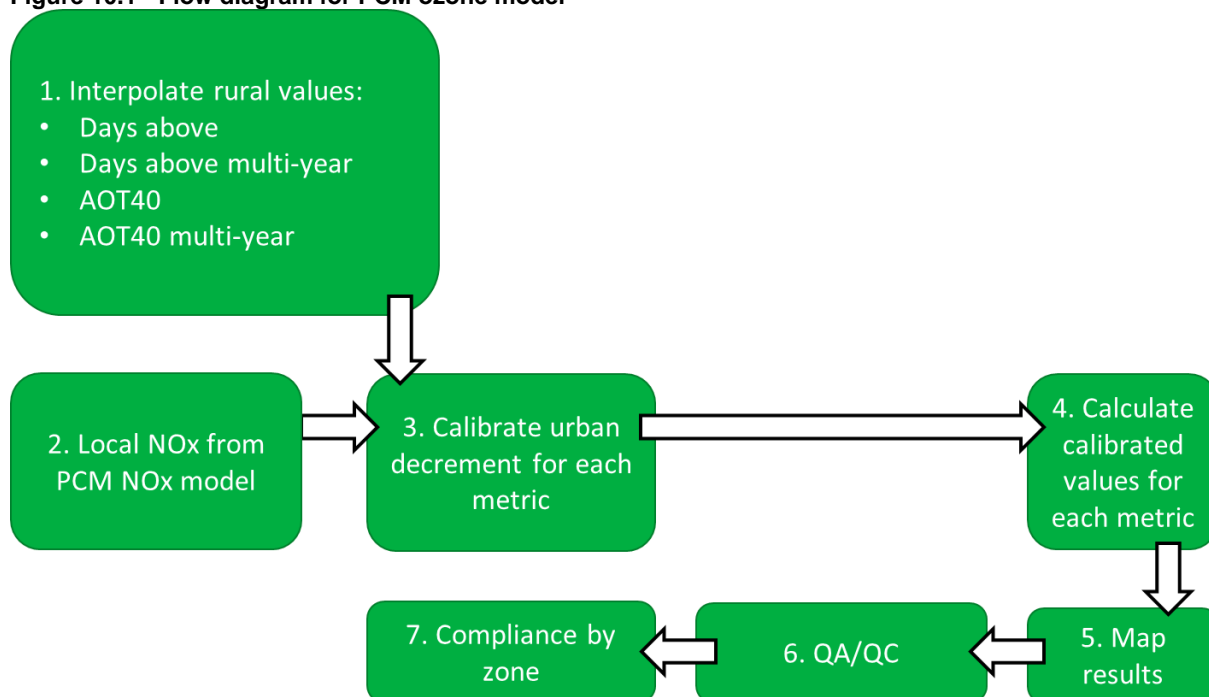

10.1.3 Overview of the PCM model for ozone

Figure 10.1 shows a simplified flow diagram of the PCM model for ozone. A summary of the PCM model method, input and assumptions for ozone is presented in Table 10.1.

10.1.4 Chapter structure

This chapter describes modelling work carried out for 2021 to assess compliance with the ozone TVs and LTOs described above. Section 10.2 describes the modelling methods and results in relation to the number of days exceeding $120 \mu\text{g m}^{-3}$ metrics. Section 10.3 describes the modelling methods and results in relation to the AOT40 metrics.

⁷ The definition of ATO40 has been given in Part 1.2 of the AQSR

Figure 10.1 - Flow diagram for PCM ozone model**Table 10.1 - PCM model method, input and assumptions summary for ozone**

Heading	Component	Details

10.2 Modelling the number of days exceeding 120 µg m⁻³ metric

10.2.1 Days greater than 120 µg m⁻³ methodology

Maps of the modelled number of days with maximum daily 8-hour mean ozone concentrations greater than 120 µg m⁻³, for comparison with the LTO (2021) and TV (averaged 2019 to 2021) are presented in Figure 10.2 and Figure 10.3 respectively.

At rural locations in the UK exceedances of 120 µg m⁻³ as a maximum daily 8-hour mean are broadly consistent over wide spatial scales. As a result, measured exceedances from rural monitoring stations have been interpolated by Inverse Distance Weighting (IDW) throughout the whole of the UK to represent the likely exceedances of this metric in the absence of any influence from local emissions of NO_x from combustion sources.

The resultant interpolated maps, however, will overestimate exceedances in urban areas, where nitric oxide emissions from combustion sources deplete ozone concentrations. This effect has been accounted for by adding an empirically derived urban ozone decrement, expressed as a percentage. The percentage decrement is defined as follows:

$$\% \text{ decrement} = 100 * ((\text{measured concentrations} - \text{rural interpolated concentration}) / \text{rural interpolated concentration})$$

The derivation of a coefficient relating the percentage decrement to the modelled local NO_x concentration is shown in Figure 10.4 and Figure 10.5. The local NO_x component is calculated as the sum of contributions from local point and area sources of NO_x emissions, calculated as described in Section 4.3.

Figure 10.4 shows the decrement plot for days greater than 120 µg m⁻³ in 2021 (the LTO for human health metric) and Figure 10.5 shows the decrement plot for days greater than 120 µg m⁻³ between 2019 and 2021 (the TV for human health metric). For some monitoring sites the decrement is positive, indicating that the measured number of days exceeding 120 µg m⁻³ is higher than the corresponding estimated rural value i.e. that the urban influence for these sites is not properly represented in the model. The cluster of low values close to the origin of these plots largely consists of the rural sites, at which there will be little difference between the rural estimated number of days exceeding 120 µg m⁻³ and the measured value. This helps to anchor the relationship to the origin. Percentage urban increments of -100% indicate that there were no measured exceedances of 120 µg m⁻³ at that monitoring site.

The calculated decrement is then used to correct the number of days where ozone concentrations are greater than 120 µg m⁻³ at rural sites, used for the interpolated maps:

$$\text{Corrected days above } 120 \mu\text{g m}^{-3} \text{ map} = \text{interpolated rural map} + \text{decrement}$$

The decrement is a negative value and so reduces the concentration presented in the interpolated rural map to account for the reduction in ozone concentrations due to reaction with NO. Where the results of the expression predict a number of days less than 0.5, the predicted value is rounded to zero.

Figure 10.2 - Estimated number of days with an 8-hour mean ozone concentration above 120 $\mu\text{g m}^{-3}$, 2021

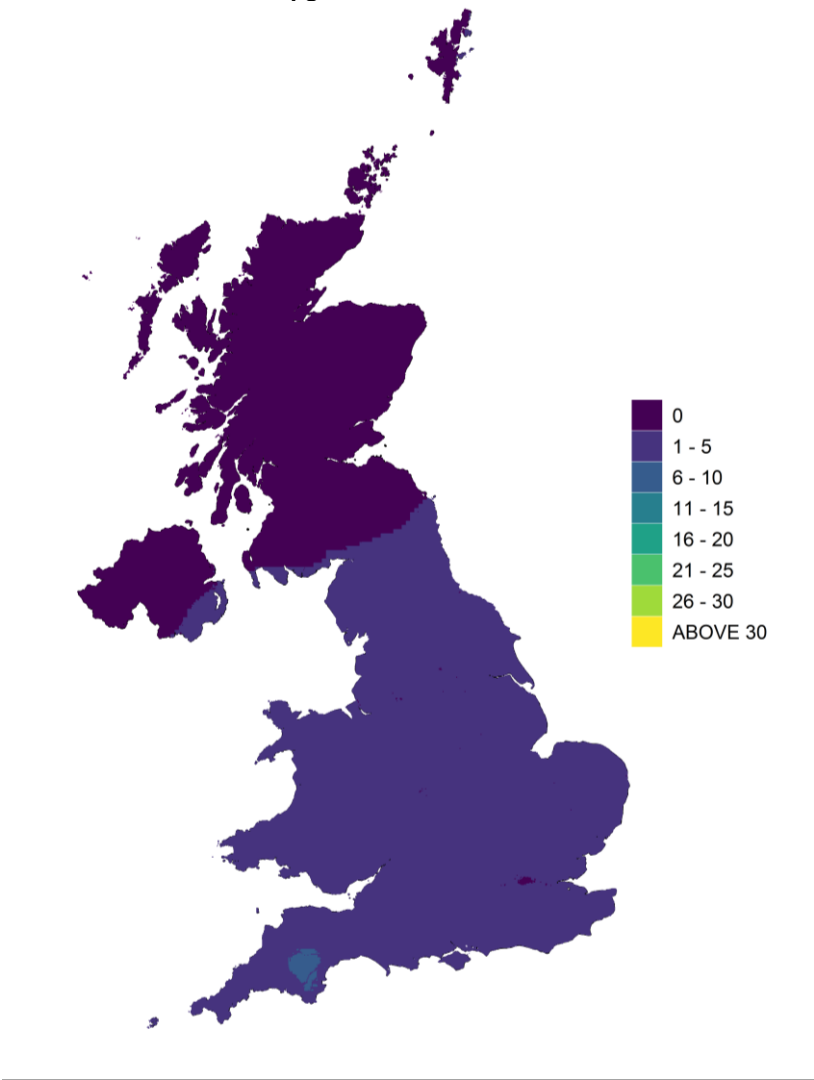

Figure 10.3 - Estimated average number of days with an 8-hour mean ozone concentration above 120 $\mu\text{g m}^{-3}$, 2019 to 2021

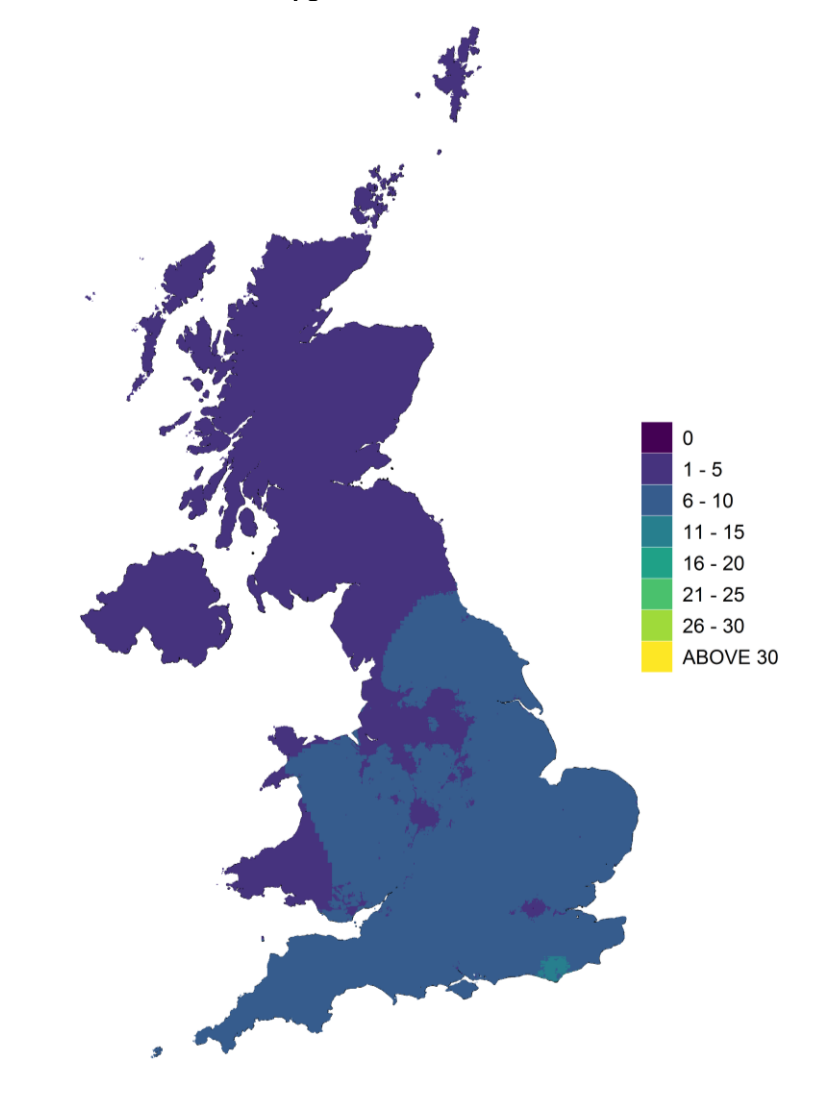

Figure 10.4 - Days greater than $120 \mu\text{g m}^{-3}$ percentage decrement in ozone concentrations, 2021**Figure 10.5 - Days greater than $120 \mu\text{g m}^{-3}$ percentage decrement in ozone concentrations, 2019-2021**

10.2.2 Verification of the number of mapped days $> 120 \mu\text{g m}^{-3}$ values

Figure 10.6 and Figure 10.7 compare the number of modelled and measured days with maximum daily 8-hour mean ozone concentrations greater than $120 \mu\text{g m}^{-3}$ in 2021 and averaged 2019-2021 at background locations, respectively. Both the national network sites used to calibrate the models and

the verification sites are shown. Lines representing $y = x + 50\%$ and $y = x - 50\%$ are also shown, as this is the AQSR data quality objective for modelled ozone concentrations – see Section 1.5.

Figure 10.6 - Verification of background number of days $> 120 \mu\text{g m}^{-3}$ model 2021

Figure 10.7 - Verification of background number of days $> 120 \mu\text{g m}^{-3}$ model 2019-2021

Figure 10.6, Figure 10.7 and Table 10.2 show that, on average, the agreement between model estimates and measurement is good for the number of days greater than $120 \mu\text{g m}^{-3}$ for the LTO and TV compared with measurements at verification sites. For both metrics, the agreement between model estimates and measurement is good for National network sites, which reflects that these measurements are part of the calibration process. The R^2 value for the verification sites, shown in Table 10.2 is lower for both metrics. There are few independent ozone monitoring sites available for model verification.

Table 10.2 - Summary statistics for comparison between modelled and measured number of days exceeding $120 \mu\text{g m}^{-3}$ as a maximum daily 8-hour mean

		Mean of measurements (days)	Mean of model estimates (days)	R^2	% outside DQO	No. sites
National network	2021	1.8	1.8	0.42	35%	55
Verification sites	2021	2.9	2.1	0.00	40%	20
National network	2019-2021	5.0	5.1	0.70	18%	65
Verification sites	2019-2021	6.2	6.9	0.28	25%	20

10.3 Modelling the AOT40 vegetation metric

10.3.1 AOT40 methodology

Maps of modelled AOT40 for comparison with the LTO (2021) and TV (averaged 2017 to 2021) are presented in Figure 10.8 and Figure 10.9 respectively.

The AOT40 vegetation metrics for 2021 and the averaged metric for 2017-2021 were calculated from measured data at rural monitoring stations in the AURN. These data were interpolated by Inverse Distance Weighting (IDW) to produce a rural map.

An urban decrement term was subsequently defined for those monitoring stations in the AURN and the rural map to correct for the depletion of ozone in areas close to sources of NO. As for the days above $120 \mu\text{g m}^{-3}$ metric, the decrement is closely related to the annual mean NO_x concentration, and has been defined in a similar fashion, using a percentage decrement in ozone concentrations associated with local NO_x concentrations.

Using the same methodology discussed in Section 10.2.1 for the days greater than $120 \mu\text{g m}^{-3}$ maps, the decrement was then used to correct the final AOT40 maps:

$$\text{Corrected AOT40 map} = \text{interpolated rural map} + \text{decrement}$$

The relationships between the decrement and modelled NO_x concentrations for 2021 and 2017-2021 averaged metrics are presented in Figure 10.10 and

Figure 10.11 respectively.

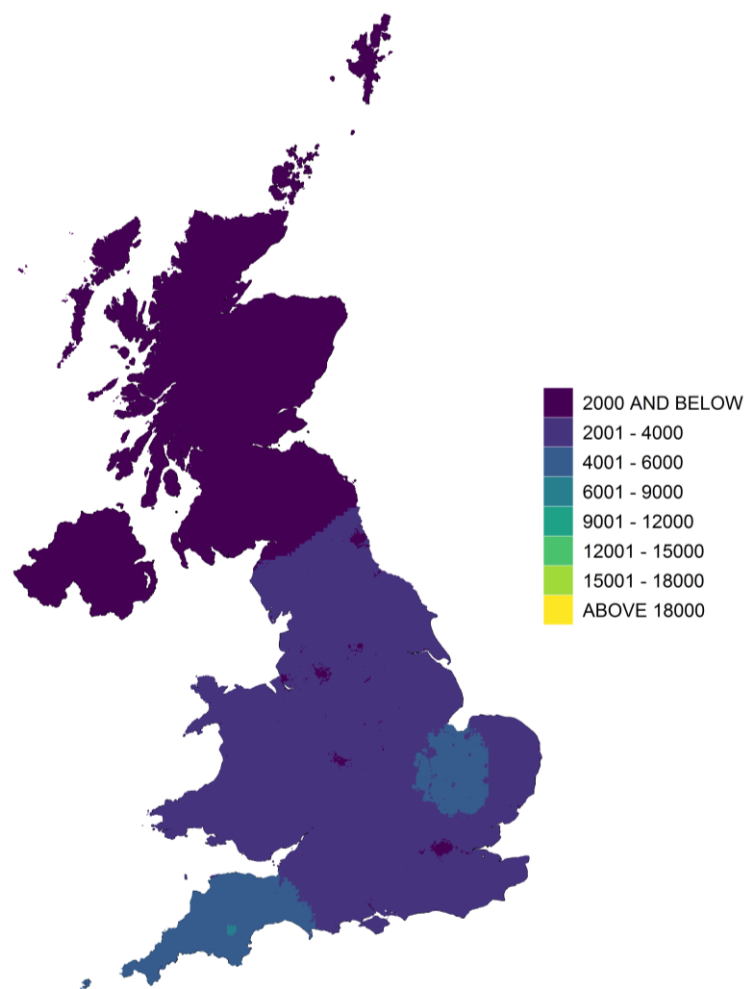

Figure 10.8 - Estimated AOT40 vegetation metric, 2021 ($\mu\text{g m}^{-3}$ hours)Figure 10.9 - Estimated AOT40 vegetation metric, averaged 2017-2021 ($\mu\text{g m}^{-3}$ hours)

Figure 10.10 - AOT40 percentage decrement in ozone concentrations, 2021**Figure 10.11 - AOT40 percentage decrement in ozone concentrations, 2017-2021**

10.3.2 Verification of mapped AOT40 values

Figure 10.12 and Figure 10.13 show a comparison of modelled and measured AOT40 metrics in 2021 and averaged 2017-2021 at background locations. Both the national network sites used to calibrate the models and the verification sites are shown. Lines representing $y = x + 50\%$ and $y = x - 50\%$ are also shown, as this is the AQSR data quality objective for modelled ozone concentrations – see Section 1.5.

Figure 10.12 - Verification of background AOT40 vegetation model, 2021**Figure 10.13 - Verification of background AOT40 vegetation model, 2017-2021**

Model performance for both the LTO and TV for the AOT40 metrics is similar to that for the days greater than $120 \mu\text{g m}^{-3}$. The R^2 values are relatively poor for the verification sites for both metrics. However, there the R^2 value is higher for the LTO and there are fewer sites outside the DQO than for the days greater than $120 \mu\text{g m}^{-3}$ for both metrics.

Table 10.3 - Summary statistics for comparison between modelled and measured AOT40 vegetation metric

		Mean of measurements ($\mu\text{g m}^{-3}$ hours)	Mean of model estimates ($\mu\text{g m}^{-3}$ hours)	R^2	% outside DQO	No. sites

11 Arsenic, Cadmium, Nickel and Lead

11.1 Introduction

11.1.1 Target and Limit values

A single limit value for ambient lead (Pb) concentrations is set out in the AQSR (legislation.gov.uk, 2010). This limit value has been specified for the protection of human health and came into force from 01/01/2005. The limit value is an annual mean concentration of $0.5 \mu\text{g m}^{-3}$.

The target values (TV) for As, Cd and Ni included in the AQSR are listed in Table 11.1. The regulations states that all necessary measures not entailing disproportionate costs to ensure that the target values are not exceeded after the compliance date should be taken.

Table 11.1 - Target values for As, Cd, and Ni

Pollutant	Averaging period	TV (ng m^{-3})	Date after which the TV is not to be exceeded
As	Calendar year	6	31 December 2012
Cd	Calendar year	5	31 December 2012
Ni	Calendar year	20	31 December 2012

11.1.2 Annual mean models

Maps of annual mean As, Cd, Ni and Pb concentrations in 2021 at background locations are shown in Figure 11.2, Figure 11.3, Figure 11.4 and Figure 11.5 respectively. These maps are presented in ng m^{-3} , where $1000 \text{ ng m}^{-3} = 1 \mu\text{g m}^{-3}$.

11.1.3 Overview of the PCM models for As, Cd, Ni and Pb

Figure 11.1 shows a simplified flow diagram of the PCM models for As, Cd, Ni and Pb. A summary of the PCM model method, input and assumptions for these pollutant models is presented in Table 11.2.

Figure 11.1 - Flow diagram for PCM As, Cd, Ni and Pb models

Heading	Component	Details
General	Pollutant	As, Cd, Ni, Pb
	Year	2021
	Locations modelled	Background
	Metric	Annual mean
Input data	Emission inventory	NAEI 2020 (scaled to 2021)
	Energy projections	Energy Projections 2021
	Road traffic counts	2021 (scaled from 2020 where not available)
	Road transport activity projections	DfT (2021) car sales projections, TfL traffic fleet projections for London (2021)
	Road transport emission factors	COPERT 5.4(COPERT 5.4, 2020)
	Measurement data	2021
	Meteorological data	WRF (see Appendix 4 – WRF meteorology)
	Regional	See details under “pollutant specific” heading
Model components	Large point sources	285 (As), 269 (Cd), 275 (Ni) and 286 (Pb) sources modelled using ADMS 5.2.
	Small point sources	PCM dispersion kernels generated using ADMS 5.2.
	Fugitive point sources	PCM dispersion kernels generated using ADMS 5.2. Fugitive emissions estimated as a proportion of reported emissions.
	ETS point sources	PCM dispersion kernels generated using ADMS 5.2.
	Large ETS point sources	54 (As), 61 (Cd), 50 (Ni) and 62 (Pb) sources modelled using ADMS 5.2.
	Area sources	PCM dispersion kernels generated using ADMS 5.2. Time varying emissions for road transport and domestic sources.
	Roadside increment	n/a
Calibration	Model calibrated?	No
	Number of background stations in calibration	n/a
	Number of traffic stations in calibration	n/a
Pollutant specific	Regional primary particles	Calculated using the TRACK receptor oriented, Lagrangian statistical model, scaled by applying heavy metal to PM ₁₀ emission ratio. Additional factor applied for As, Cd and Pb.
	Regional dusts from re-suspension of soils	Modelled using information on land cover (bare soil, root and cereal crops) and dispersion kernel incorporating emissions and dispersion processes. Multiplied by heavy metal concentration in soil and empirical enhancement factor.
	Dusts from re-suspension due to vehicle activity	Modelled using information on vehicle movements on major roads (HDV) and dispersion kernel incorporating emissions and dispersion processes. Multiplied by heavy metal concentration in soil and empirical enhancement factor.

	Fine scale modelling (Ni only)	<ul style="list-style-type: none"> • Contribution of emissions from an industrial source at Pontardawe modelled at 20 m spatial resolution using local meteorological measurements. Model includes building effects and terrain. • Contribution of emissions from an industrial source in Sheffield modelled at 50 m spatial resolution using local meteorological measurements and incorporating local terrain effects.
--	--------------------------------	--

11.1.4 Outline of the annual mean models for As, Cd, Ni and Pb

The maps of background concentrations of As, Cd, Ni and Pb have been calculated by summing contributions from different sources:

- Large point source emissions
- Small point source emissions
- Fugitive point source emissions
- Point sources with emissions estimates for air quality pollutants based on reported carbon emissions (ETS points)
- Area sources related to domestic combustion
- Area sources related to road traffic
- Other area sources
- Regional primary particles
- Re-suspension from bare soils
- Re-suspension as a result of vehicle movement

These components are aggregated to a single 1 km x 1 km background grid value for each pollutant.

11.1.5 Chapter structure

This chapter describes modelling work carried out for 2021 to assess compliance with the Pb limit value and As, Cd, and Ni target values described above. Emission estimates are described in Section 11.2, Section 11.3 describes the modelling methods, and the modelling results are presented in Section 11.4 to Section 11.7. The source apportionment of ambient concentrations is discussed in each pollutant results section and is often very different from the split for total national emissions. Ambient concentrations are influenced by the location and release characteristics of the emissions and are also influenced by sources not included in the inventory, such as re-suspension.

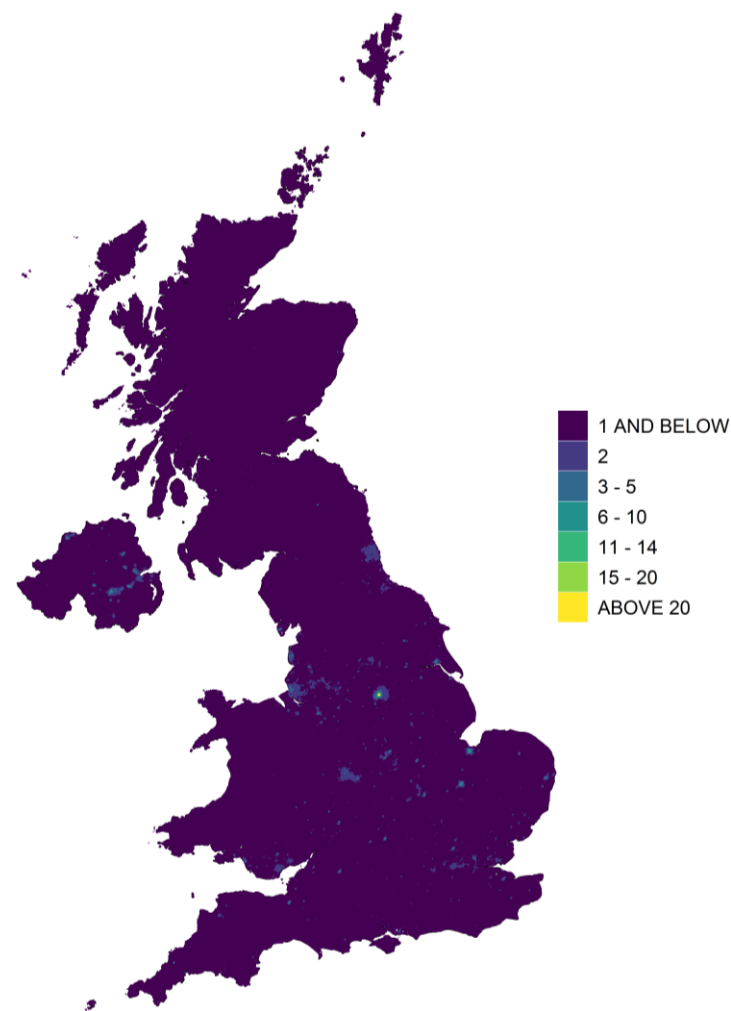

Figure 11.5 - Annual mean background Pb concentration, 2021 (µg m⁻³)

11.2 Emissions

Estimates of the emissions of Heavy Metals from the UK National Atmospheric Emissions Inventory 2020 (NAEI 2020) have been used in this study (Churchill *et al.*, 2022). Emissions projections have been provided by the NAEI (Personal communication from Ben Pearson, 2022) based on BEIS EEP 2021 energy and emissions projections (BEIS, 2022). UK total emissions for 2021 split by SNAP code for As, Cd, Ni and Pb are shown in Figure 11.6, Figure 11.7, Figure 11.8 and Figure 11.9 respectively, with the coding described in Table 4.2.

Figure 11.6 shows that arsenic emissions in 2021 are dominated by two main sources:

- SNAP 3: Industrial combustion
- Other point sources (SNAP 4, 5, 6 and 9).

Emissions of arsenic are primarily from the combustion of solid fuel. The majority of emissions are estimated to be from the burning of treated wood. There are no reliable estimates of the extent of this activity, and since the emission factor for this source is also very uncertain, the total emission estimate for this source is highly uncertain.

Figure 11.7 shows total emissions of cadmium for 2021 are dominated by four main sources:

- SNAP 7: Road transport (exhaust emissions)
- SNAP 3: Industrial combustion
- Combustion point sources (SNAP codes 1, 2 and 3)
- SNAP 2: Domestic combustion.

Figure 11.8 shows the 2021 nickel emissions are dominated by two main sources:

- SNAP 2: Domestic combustion
- SNAP 3: Industrial combustion.

Nickel emissions to the atmosphere arise primarily from the combustion of liquid fuels and solid fuels derived from petroleum (petroleum coke and solid smokeless fuels).

Figure 11.9 shows that overall lead emissions for 2021 are dominated by four main sources:

- SNAP 7: Road transport (brake and tyre wear)
- Combustion point sources (SNAP codes 1, 2 and 3)
- SNAP 3: Industrial combustion
- Other point sources (SNAP 4, 5, 6 and 9)

Lead emissions are largely from point sources, road transport brake and tyre wear, combustion in industry and solvent use (specifically Fireworks process emissions).

Figure 11.8 - Total UK Ni emissions for 2021 by SNAP code scaled using Covid factors from NAEI 2020**Figure 11.9 - Total UK Pb emissions for 2021 by SNAP code scaled using Covid factors from NAEI 2020**

11.3 The model

11.3.1 Contribution from large point sources

Contributions to ground level annual mean heavy metal concentrations from point sources (those with annual emissions of greater than the thresholds listed by pollutant in Table 11.3, or for which emission release characteristics are known) in the NAEI 2020 were estimated by modelling each source explicitly using the atmospheric dispersion model ADMS 5.2 and sequential meteorological data for 2021 from the WRF model, as described in Appendix 4 – WRF meteorology. Concentrations were calculated for a 99 km x 99 km square composed of a regularly spaced 1 km x 1 km resolution receptor grid. Each receptor grid was centred on the point source. The total number of point sources modelled explicitly is given in Table 11.3. For each large point source information was retrieved from the PCM stack parameters database (as described in Section 4.3.1). The NAEI emissions for point sources for 2020 were scaled in order to provide values for 2021 as described in Section 4.3.1.

The Vale Clydach refinery in South Wales is located within the Pontardawe Valley a few miles from the Pontardawe Tawe Terrace monitoring station. To provide the best estimate of Ni concentrations in this area, reported 2021 emissions and updated stack parameters for this site were provided by the site operator and incorporated into the large points modelling for Ni.

A factor of 0.3 has been applied to the modelled contribution of large point sources to As concentrations, consistent with the 2013, 2014, 2015, 2016, 2017, 2018, 2019 and 2020 modelling. Factors of unity have been applied to the modelled contribution from large point sources to concentrations of Ni, Pb and Cd. Factors were chosen to provide the best agreement of total model predictions with measured heavy metal concentrations. Activity levels for combustion of coal in industry were about 50% higher in the 2012 NAEI than in the 2011 NAEI and have remained at this higher level in subsequent inventories. There has been no clear trend or change in ambient As concentrations measured in the UK over this period. A factor of less than unity was therefore required for industrial emissions of As.

The NAEI 2020 includes point source emissions estimates derived from carbon emissions data reported under the EU-Emissions Trading Scheme (ETS), most recently described in (Tsagatakis *et al.*, 2022). These point sources are referred to as ETS points in this report. These derived air quality pollutant emissions are particularly uncertain and therefore in previous assessments (e.g. (Brookes *et al.*, 2017)) emissions were capped at reporting thresholds and treated as small point sources. For the 2016, 2017, 2018, 2019 and 2020 assessments (Brookes *et al.*, 2019b, 2019a, 2020, 2021; Pugsley *et al.*, 2022) the NAEI recommended treating the ETS points that have emissions greater than the large points modelling threshold as large points and not to apply a cap (Personal communication from Ben Pearson, 2022). The 2021 assessment continues this approach. Thus, those ETS point sources of As, Cd, Ni and Pb meeting the criteria for the treatment of large point sources described above, were modelled as an additional set of large point sources (using the approach described above). The total number of ETS point sources modelled explicitly is given in Table 11.3. ETS points that were not classified as large point sources were modelled using the small and fugitive points approach described next.

11.3.2 Contributions from small point and fugitive sources

The contributions to ambient concentrations from fugitive and small point sources (those without stack parameters datasets and annual emissions less than or equal to values displayed in Table 11.3) in the NAEI 2020 were modelled using a small points model. The NAEI 2020 emissions for fugitive and small point sources have been scaled to 2021 using the same source sector specific projection factors applied to the large point sources.

The models consist of separate ‘in-square’ and ‘out-of-square’ components, in which concentrations are estimated using a point source dispersion kernel. The dispersion kernel for small points has been calculated by using the dispersion model ADMS 5.2 to model the dispersion of unit emissions from a central source to a grid of receptors at a spatial resolution of 1 km x 1 km squares with the stack characteristics as presented in Table 11.4. Hourly sequential meteorological data from the WRF model in 2021 has been used to construct the dispersion kernels. The greatest concentration would be expected close to the point of emission. The receptor for the central grid square within the dispersion kernel is, however, at exactly the same location as the point of release. The concentration at this location is therefore zero. The value for the central grid square within the dispersion kernel has therefore been assigned to be equal to the highest of the values for the adjacent grid squares.

A factor of 0.3 has been applied to the modelled contribution of small point sources to As concentrations, consistent with the 2013, 2014, 2015, 2016, 2017, 2018, 2019 and 2020 modelling and the treatment of large point sources. Factors of unity have been applied to the modelled contribution from small point sources to concentrations of Ni, Pb and Cd. Factors were chosen to provide the best agreement of total model predictions with measured heavy metal concentrations.

Table 11.3 - Thresholds to determine modelling method, and number of large point sources for 2021

Pollutant	Tonnes per year	Number of large point sources	Number of large ETS point sources
As	0.025	285	54
Cd	0.025	269	61
Ni	0.05	275	50
Pb	1.2	286	62

Table 11.4 - Stack release parameters used to characterise emissions from point sources with no available stack parameters

Variable	Parameters
Stack height	15 m
Diameter	1 m
Temperature	15°C
Emission rate as PM ₁₀	1g/s
Surface roughness at dispersion site	0.5 m
Surface roughness at met site	0.02 m

Characterising the amount of fugitive heavy metal emission from industrial plant is notoriously difficult. For the modelling of Cd, Ni and Pb concentrations, assuming a fugitive emission of 0.05 times the reported emission was found to provide the best agreement with the available measurements. For the modelling of As, a fugitive emission 0.015 times the reported emission was assumed.

The emission release parameters for fugitive sources are provided in Table 11.5. Once again, the value for the central grid square within the dispersion kernel has been set to the maximum of the values in the surrounding grid squares.

Table 11.5 - Stack release parameters used to characterise fugitive emission release

Variable	Parameters
Stack height	10 m
Diameter	1 m
Temperature	15°C
Emission rate as PM ₁₀	1g/s
Surface roughness at dispersion site	0.5 m
Surface roughness at met site	0.02 m

11.3.3 Contributions from local area sources

The 2021 area source emissions maps for heavy metals have been calculated from the NAEI 2020 emissions maps following the method described in Section 4.3.5. ADMS derived dispersion kernels have been used to calculate the contribution to ambient concentrations on a 1 km x 1 km receptor grid, from the area source emissions within a 33 km x 33 km square surrounding each receptor. Hourly sequential meteorological data from the WRF model in 2021 has been used to construct the dispersion kernels, as described in Appendix 5 – Dispersion kernels for the area source model. Revised methods introduced in the 2011 assessment (Brookes *et al.*, 2012) for modelling the contributions to As, Cd, Ni and Pb from SNAP 2 (domestic and non-domestic combustion) and SNAP 3 (combustion in industry) area sources were used and have been described in Section 4.3.5.

A factor of 0.3 has been applied to the modelled contribution of domestic area sources to Ni concentrations. A factor of 0.3 has been applied to the modelled contribution of road traffic sources to Ni concentrations to account for a revision to the NAEI that incorporates a revised emission factor for the contribution from engine lubricants. Factors of unity have been applied to the modelled contribution from area sources to concentrations of Pb and Cd, and to other area source types for As

and Ni modelling. Factors were chosen to provide the best agreement of total model predictions with measured heavy metal concentrations.

For certain sectors (noted within each pollutant results section below) caps have been applied to emissions based on expert judgement of the model results to address known artefacts in the area source emissions grids and to reconcile the model results with the measured data at each monitoring site.

11.3.4 Contribution from long range transport of primary particulate matter

The contribution to ambient concentrations from long range transport of heavy metals was derived from estimates of regional primary particulate matter used in the 2021 PCM model for PM₁₀ mass (Section 6.3.4). The contribution of long-range transport sources to ambient heavy metal concentrations was derived by calculating a fraction of the PM mass for each heavy metal. This fraction was estimated as the ratio of the UK total emissions for each metal for each SNAP sector to the total PM₁₀ emission for that sector. The following scaling factors for long range transport of primary particulate matter were then applied: 4.5 for As, 2.0 for Cd, 0.4 for Ni and 3.0 for Pb. These factors chosen to provide the best agreement of total model predictions with measured heavy metal concentrations.

11.3.5 Heavy metal contribution from re-suspension

The 2021 model for heavy metal concentrations includes a contribution to ambient concentrations from re-suspension calculated in the same way as in the 2011 models (Brookes *et al.*, 2012). The contributions from two processes have been included:

- Regional PM dusts from re-suspension of soils and
- PM dusts from re-suspension due to vehicle activity.

The heavy metal contribution from re-suspension has been calculated by using the methods suggested by (Abbott, 2008). The methods used to estimate the total PM mass from these processes are detailed in Section 6.3.5.

(Abbott, 2008) also suggested a method for estimating the contributions to the ambient concentrations of heavy metals from soil and vehicle related re-suspension processes. The maps of PM mass from re-suspension of soils and re-suspension associated with vehicle movements can be used to estimate the contributions to the ambient concentration of heavy metals using a combination of information on the heavy metal content of soils and enhancement factors.

The National Soil Inventory (<http://www.landis.org.uk/data/natmap.cfm>) provides a data set of As, Cd, Ni and Pb concentrations in topsoil at 5 km resolution throughout England and Wales. Measurement data on heavy metals concentration in topsoil for other areas of the UK is available from the Geochemical Atlas of Europe developed under the auspices of the Forum of European Geological Surveys (FOREGS) (<http://weppi.gtk.fi/publ/foregsatlas/>). These data were interpolated onto a 1 km x 1 km grid. The predicted annual PM emission rates and the contribution to atmospheric concentrations were multiplied by the topsoil concentrations to estimate the annual metal re-suspension rates and the contributions to atmospheric concentrations of the heavy metals.

There is some evidence that metal concentrations in the surface soils are higher than in the underlying topsoil. EMEP have suggested that there may be some enhancement of the metal content of the re-suspended dust because the metals may form complexes with humic matter (Abbott, 2008). (Abbott, 2008) carried out regression analyses of measured heavy metal concentrations against the combined model predictions for sites in the UK Rural Heavy Metal Network. This analysis suggested that there may be other mechanisms by which heavy metals are concentrated in the small particle fraction of soils. For example, much of the metal content may be present as the result of historical deposition of small particles or the application of sewage sludge and farmyard slurries. These materials may only be loosely bonded to the surface of the soil particles. The fine particles released by re-suspension mechanisms would therefore be likely to contain a much higher concentration of metals than the underlying topsoil. The enhancement factors listed in Table 11.6 have been chosen to provide the best agreement of total model predictions with measured heavy metal concentrations. The factors are broadly consistent with the regression coefficients determined by (Abbott, 2008).

Caps have been applied for the contribution generated from re-suspension of soil for some of the heavy metals. The values have been chosen as an estimate of the maximum likely concentration generated from this source and are also listed in Table 11.6.

Table 11.6 - Heavy metal enhancement factors used in the assessment

Pollutant	Enhancement factor	Maximum concentration (ng m ⁻³)
As	12.5	3.5
Cd	25	2.5
Ni	2	5
Pb	25	5

11.4 Arsenic Results

11.4.1 Introduction

The map of modelled annual mean As concentrations is shown in Figure 11.2. There were no modelled or measured exceedances of the target value of 6 ng m⁻³ in 2021.

11.4.2 Verification of mapped concentrations

A comparison between modelled and measured annual mean As concentrations in 2021 at monitoring site locations is shown in Figure 11.10. This figure includes lines to represent the AQSR data quality objective for modelled annual mean As concentrations: $y=x-60\%$ and $y=x+60\%$ (see Section 1.5).

Summary statistics for modelled and measured As concentrations are listed in Table 11.7, including the percentage of sites at which modelled concentrations are outside of the data quality objectives (DQOs), and the total number of sites included in the analysis.

The means of measured and modelled concentrations are in reasonable agreement for all site types, with all sites falling within the DQOs. However, the agreement between measured and modelled concentrations on a site-by-site basis (quantified using R^2) is poor for urban background monitoring sites but is reasonably good at industrial and rural monitoring locations.

It should be noted that non-emission inventory sources (such as fugitive, re-suspension and long-range transport of primary PM) result in additional uncertainty when compared with a pollutant such as NO_x, for which the source apportionment is better known.

Figure 11.10 - Verification of annual mean As across all sites.

Table 11.7 - Summary statistics for comparison between modelled and measured annual mean As concentrations at different monitoring sites, 2021.

	Mean of measurements (ng/m ³)	Mean of model estimates (ng/m ³)	R ²	% of sites outside DQO of $\pm 60\%$	Number of sites in assessment
Industrial sites	0.77	0.83	0.68	0%	6
Urban background sites	0.70	0.78	0.22	0%	7
Roadside sites	0.94	0.76	1.00	0%	2
Rural sites	0.46	0.48	0.80	0%	8
All	0.66	0.68	0.63	0%	23

11.4.3 Source apportionment

Figure 11.11 shows the modelled As contribution from different sources at monitoring site locations. Measured concentrations at the sites are also presented, giving an indication of the level of agreement between modelled and measured concentrations. This analysis suggests that the main sources of arsenic are long range transport primary, resuspension and industry.

Figure 11.11 - Annual mean As source apportionment at monitoring sites in 2021.

11.5 Cadmium Results

11.5.1 Introduction

The map of modelled annual mean Cd concentrations is shown in Figure 11.3. There were no modelled or measured exceedances of the target value of 5 ng m^{-3} in 2021.

11.5.2 Verification of mapped concentrations

A comparison between modelled and measured annual mean Cd concentrations in 2021 at monitoring site locations is shown in Figure 11.12. This figure includes lines to represent the AQSR data quality objective for modelled annual mean Cd concentrations: $y=x-60\%$ and $y=x+60\%$ (see Section 1.5).

Summary statistics for modelled and measured Cd concentrations are listed in Table 11.8, including the percentage of sites at which modelled concentrations are outside of the DQOs and the total number of sites included in the analysis.

The agreement between measured and modelled concentrations on a site-by-site basis (quantified using R^2) is good for rural monitoring locations, but poor for industrial and urban background monitoring locations.

It should be noted that non-emission inventory sources (such as fugitive, re-suspension and long-range transport of primary PM) result in additional uncertainty when compared with a pollutant such as NO_x , for which the source apportionment is better known.

Figure 11.12 - Verification of annual mean Cd across all sites.

Table 11.8 - Summary statistics for comparison between modelled and measured annual mean Cd concentrations at different monitoring sites, 2021.

	Mean of measurements (ng/m ³)	Mean of model estimates (ng/m ³)	R ²	% of sites outside DQO of ±60%	Number of sites in assessment
Industrial sites	0.50	0.23	0.56	33%	6
Urban background sites	0.18	0.29	0.02	57%	7
Roadside sites	0.25	0.18	1.00	100%	2
Rural sites	0.07	0.08	0.94	13%	8
All	0.23	0.19	0.07	39%	23

11.5.3 Source apportionment

Figure 11.13 shows the modelled Cd contribution from different sources at monitoring site locations. Measured concentrations at the sites are also presented, giving an indication of the level of agreement between modelled and measured concentrations. This analysis suggests that at those sites where the highest concentrations are measured, the main sources of cadmium are industry, resuspension, and long-range transport primary. Industrial sites have larger quantities of emissions assigned to industry than non-industrial sites.

Figure 11.13 - Annual mean Cd source apportionment at monitoring sites in 2021.

11.6 Nickel Results

11.6.1 Introduction

The method used to estimate ambient Ni concentrations across the UK is described in Section 11.3 above.

A cap of 30 t/a/km² also applied to shipping emissions.

The map of modelled annual mean Ni concentrations is shown in Figure 11.4. Historically there have been issues with compliance for nickel and this was the case in 2021. Detailed local modelling carried out to characterise the impact of emissions on ambient concentrations at locations associated with exceedances is discussed in Section 11.6.4.

11.6.2 Verification of mapped concentrations

A comparison between modelled and measured annual mean Ni concentrations in 2021 at monitoring site locations is shown in Figure 11.14 ((a) at full scale showing all sites, and (b) on an expanded scale to better show performance at lower concentrations). This figure includes lines to represent the AQSR data quality objective for modelled annual mean Ni concentrations: $y=x-60\%$ and $y=x+60\%$ (see Section 1.5).

The results for several monitoring site locations included in Figure 11.14 (Pontardawe Tawe Terrace, Sheffield Tinsley, and Sheffield Devonshire Green) are covered by more detailed local modelling assessments (see Section 11.6.4). A modelled Ni concentration of 25.0 ng m⁻³ has been reported for the 2021 compliance assessment modelling for the 1 km grid square containing the Pontardawe Tawe Terrace monitoring site, equal to the measured value for this monitoring site. For model verification the modelled value including the local detailed modelling was also 25.0 ng m⁻³ hence the modelled and measured values in Figure 11.14 for Pontardawe Tawe Terrace are equal. Modelled Ni concentrations of 25.1 ng m⁻³ and 2.9 ng m⁻³ have been reported for the 2021 compliance assessment modelling for the 1 km grid squares containing the Sheffield Tinsley and Sheffield Devonshire Green monitoring sites respectively taking into account the average (mean) of the detailed modelling results per 1 km grid square. For model verification the measured Ni concentrations at Sheffield Tinsley and Sheffield Devonshire Green are 13.6 ng m⁻³ and 2.2 ng m⁻³ respectively, while the modelled values for the 50 m grid squares containing the Sheffield monitoring sites from the local detailed modelling are 13.5 ng m⁻³ and 3.0 ng m⁻³ respectively. Hence there are small differences in the modelled and measured values in Figure 11.14 for Sheffield Tinsley and for Sheffield Devonshire Green.

Summary statistics for modelled and measured Ni concentrations are listed in Table 11.9, including the percentage of sites for which the modelled values are outside of the DQOs as well as the total number of sites included in the analysis.

The agreement between measured and modelled concentrations on a site-by-site basis are good for all monitoring sites as quantified using R², and poorer in terms of comparison of the measured and modelled mean concentrations where there is a tendency for the model to overestimate at lower measured concentrations. The results for the Pontardawe Tawe Terrace, Sheffield Tinsley and Sheffield Devonshire Green sites are discussed in Section 11.6.4.

It should be noted that non-emission inventory sources (such as fugitive, re-suspension and long-range transport of primary PM) result in additional uncertainty when compared with a pollutant such as NO_x, whose source apportionment is better known.

Figure 11.14 - Verification of annual mean Ni across all sites.**(a) Full scale showing all sites****(b) Expanded scale, Tawe Terrace and Sheffield Tinsley results off scale**

Table 11.9 - Summary statistics for comparison between modelled and measured annual mean Ni concentrations at different monitoring sites, 2021.

	Mean of measurements (ng/m ³)	Mean of model estimates (ng/m ³)	R ²	% of sites outside DQO of ±60%	Number of sites in assessment
Industrial sites	8.01	7.93	0.97	50%	6
Urban background sites	2.58	1.92	0.13	57%	7
Roadside sites	5.69	1.42	1.00	50%	2
Rural sites	0.38	0.50	0.69	25%	8
All	3.50	0.31	0.53	43%	23

11.6.3 Source apportionment

Figure 11.15 shows the modelled Ni contribution from different sources at monitoring site locations. Measured concentrations at the sites are also presented, giving an indication of the level of agreement between modelled and measured concentrations. This analysis suggests that the main sources of nickel are long range transport primary, industry, domestic and resuspension. Emissions from local industrial point sources are important for Pontardawe Brecon Road, Pontardawe Tawe Terrace, and Sheffield Tinsley, and this is discussed in detail in Section 11.6.4.

Figure 11.15 - Annual mean Ni source apportionment at monitoring sites in 2021

11.6.4 Detailed comparison of modelled results with the target value

11.6.4.1 Introduction

There were exceedances in four zones in 2021, one measured (Swansea Urban Area) and three modelled (Sheffield Urban Area, South Wales and Yorkshire and Humberside). Results of the assessment in terms of comparisons of the modelled concentrations with the TV have been reported in e-Reporting Data flow G published on UK-Air (*UK-Air*, 2022). Exceedance of the Ni TV in all four zones have been reported in previous years. Local monitoring and detailed modelling in the vicinity exceedances are carried out annually and inform the maximum concentration and, where applicable, area of exceedance reported in e-Reporting for each zone.

Maximum concentrations of Ni of 25 ng m⁻³ for the Swansea Urban Area and of 27 ng m⁻³ for the South Wales zones were reported. The value for the Swansea Urban Area zone was based on the annual mean Ni concentration measured at Pontardawe Tawe Terrace. This monitoring site is within the Swansea Urban Area zone but is very near to the boundary of the South Wales zone. The value for the South Wales zone was based on model results. Detailed modelling of the principal source of local nickel emissions for the exceedance in these two zones is described below in Section 11.6.4.2.

Maximum concentrations of Ni for the Sheffield Urban Area and Yorkshire and Humberside zones were reported based upon consideration of the maximum of measured concentrations within these zones, concentrations from the national modelling and detailed local modelling of the contributions of significant industrial sources within Sheffield. A maximum concentration of 225 ng m⁻³ was reported for the Sheffield zone based on the maximum of the average (mean) of exceeding 50 m grid squares from the detailed local modelling for Sheffield per 1 km grid square in the zone. Similarly, a maximum concentration of 34 ng m⁻³ was reported for the Yorkshire and Humberside zone also based on the detailed local modelling for Sheffield. Detailed modelling of the principal sources of nickel emissions for the exceedances in these zones is described below in Section 11.6.4.3.

11.6.4.2 Swansea Urban Area and South Wales Zones

Detailed dispersion modelling has been undertaken using ADMS 5.2 for the area in South Wales where exceedances of the annual mean TV of 20 ng m⁻³ have been measured in 2021. This fine-scale modelling has been used to assess the likely magnitude and spatial extent of exceedance.

Information on the Ni emissions from the principal Ni point source were provided by the site operators. The annual Ni emission from one plant was reported by the site operator to be 23.08 kg year⁻¹. The modelling was performed and scaled to provide the best fit to the monitoring data at Pontardawe Tawe Terrace.

Emissions were released from thirteen emission points distributed across the site. Building effects were included in the model, and a 6 km x 6 km area was extracted from the OS Terrain 50 dataset to allow the effect of the topographical features of the valley to be included in the model. The height of the terrain was specified at the centre of each 50 m x 50 m grid square.

Table 11.10 compares measured annual mean Ni concentrations with modelled concentrations. The modelled concentrations include a component resulting from the local industrial point source in Pontardawe and a background component from the annual modelling Ni concentrations across the UK. The model reproduces the measured concentration at Pontardawe Leisure Centre and Pontardawe Brecon Road well. Agreement is also good at Pontardawe Tawe Terrace, for which the measured concentration was used to inform the scaling of emissions estimates and thus good agreement is to be expected.

Figure 11.16 shows the modelled annual mean Ni concentration on a 20 m x 20 m grid resulting from the local industrial point source in Pontardawe and including a background component from the annual modelling of Ni concentrations across the UK. The Ni concentrations in Pontardawe were strongly influenced by the terrain in the area, as can be seen in Figure 11.16. The Swansea Valley runs south-west to north-east through the village of Pontardawe, where the point source is located. The distribution of the Ni concentrations in the vicinity of Pontardawe shows the channelling of the local wind flow by the Swansea Valley.

The conclusions from this dispersion modelling study are that Ni concentrations in both the South Wales and Swansea Urban Area zones in 2021 exceeded the Ni TV.

The source apportionment plot (Figure 11.15) and scatter plot (Figure 11.14) presented earlier in this section include the modelled contribution to ambient concentrations at the Pontardawe Tawe Terrace and Pontardawe Brecon Road sites from the local industrial point source.

Figure 11.16 - Modelled annual mean Ni concentration resulting from the local industrial point source in Pontardawe in 2021.

Table 11.10 - Comparison of annual mean measured and modelled Ni concentrations at Pontardawe Tawe Terrace, Pontardawe Leisure Centre and Pontardawe Brecon Road in 2021.

	Measured Ni (ng m ⁻³)	Modelled Ni (ng m ⁻³)
Pontardawe Tawe Terrace	25	25
Pontardawe Leisure Centre	9.0	11.5
Pontardawe Brecon Road	6.3	3.2

11.6.4.3 Sheffield Urban Area and Yorkshire and Humberside Zones

The Sheffield Tinsley monitoring station is located in the valley of the river Don to the North East of Sheffield City Centre in the Sheffield Urban Area agglomeration zone. Exceedances of the annual mean TV of 20 ng m⁻³ have been reported in previous years: 2014 and 2016 on the basis of measurements at the Sheffield Tinsley monitoring station and 2018, 2019 and 2020 on the basis of model results). The AQSR requires that actions and measures are put in place to help meet the TV following an exceedance. Reports on Measures have been published⁸ providing detail on the assessment of the exceedances reported in previous years and the actions and measures that have already been taken or are planned that will help the UK meet the Ni TV. Detailed dispersion modelling has been undertaken for the 2021 compliance assessment using ADMS 5.2 for an area in Sheffield covering the locations of the Sheffield Tinsley and Sheffield Devonshire Green monitoring stations and the principal industrial Ni sources. This fine scale modelling has been used to assess the likely magnitude and spatial extent of exceedance and takes into account work carried out for the report on measures for 2016, 2018, 2019 and 2020 for the Sheffield Urban Area agglomeration zone (Defra, 2018, 2020, 2021, 2022) in terms of related modelling work and high time resolution monitoring campaigns. For other sites with Ni measurements in the Yorkshire and Humberside zone (Scunthorpe

⁸ <https://uk-air.defra.gov.uk/library/bap-nickel-measures>

Low Santon and Scunthorpe Town) there are no reported exceedances for 2021, hence the focus of the detailed modelling has been on Sheffield.

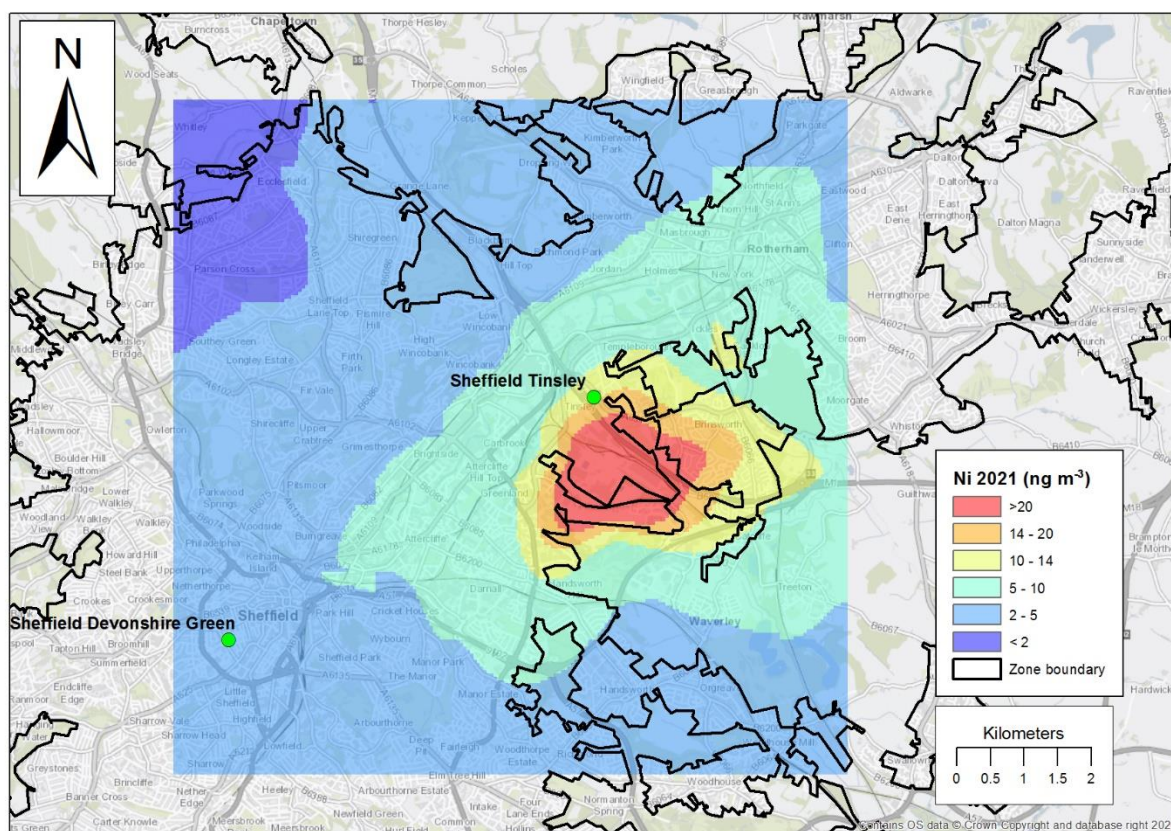

To support this detailed modelling, information on Ni emissions and release characteristics for the principal industrial Ni emission sources were provided by the Environment Agency (including data collated on sites regulated by Sheffield City Council and Rotherham Metropolitan Borough Council) and complemented by emissions data from the NAEI 2020. Emissions were released from 15 emission sources from one plant. The emissions from the plant were modelled to be released from 14 point sources and one area source. Terrain effects were included in the modelling based on OS Terrain 50.

Figure 11.17 shows the modelled annual mean Ni concentration on a 50 m x 50 m grid resulting from the principal local industrial Ni source in the Sheffield area and including a background component from the annual modelling of Ni concentrations across the UK. The best representation of concentrations at the Sheffield Tinsley monitoring station was obtained as the sum of the modelled contribution from the principal local source and the background contribution. Due to the limited emissions data from the stockyards, the emission rate from this source was scaled based on the measurement data at the Tinsley monitoring station.

The conclusions from this dispersion modelling study are that Ni concentrations in both Sheffield Urban Area and Yorkshire & Humberside zones in 2021 exceeded the Ni TV.

The source apportionment plot (Figure 11.15) and scatter plot (Figure 11.14) presented earlier in this section include the modelled contribution to ambient concentrations at the Sheffield Tinsley and Sheffield Devonshire Green sites from the local industrial Ni sources in Sheffield.

Figure 11.17 - Modelled annual mean Ni concentration resulting from the local industrial sources in Sheffield Tinsley in 2021.

11.7 Lead Results

11.7.1 Introduction

The method used to estimate the Pb ambient concentration across the UK is described in Section 11.3 above.

The map of modelled annual mean Pb concentrations is shown in Figure 11.5. There were no modelled or measured exceedances of the limit value of 0.5 µg/m³ in 2021.

11.7.2 Verification of mapped concentrations

A comparison between modelled and measured annual mean Pb concentrations in 2021 at different monitoring site locations is shown in Figure 11.18. These figures include lines to represent the AQSR data quality objective for modelled annual mean Pb concentrations: $y=x-50\%$ and $y=x+50\%$ (see Section 1.5).

Summary statistics for modelled and measured Pb concentrations are listed in Table 11.11, including the percentage of sites at which modelled concentrations are outside of the data quality objectives (DQOs), and the total number of sites included in the analysis.

The mean and distribution (quantified using R^2) of measured UK modelled concentrations agree very well for the rural monitoring sites.

It should be noted that non-emission inventory sources (such as fugitive, re-suspension and long-range transport of primary PM) result in additional uncertainty when compared with a pollutant such as NO_x, for which the source apportionment is better known.

Figure 11.18 - Verification of annual mean Pb across all sites.**Table 11.11 - Summary statistics for comparison between modelled and measured annual mean Pb concentrations at different monitoring sites, 2021.**

	Mean of measurements (ng/m ³)	Mean of model estimates (ng/m ³)	R ²	% of sites outside DQO of ±50%	Number of sites in assessment
Industrial sites	11.24	11.20	0.12	17%	6
Urban background sites	9.80	7.86	0.18	86%	7
Roadside sites	7.80	7.61	1.00	100%	2
Rural sites	2.38	2.48	0.87	0%	8
All	7.42	6.84	0.15	39%	23

11.7.3 Source apportionment

Figure 11.19 shows the modelled Pb contribution from different sources at monitoring locations. Measured concentrations at the sites are also presented, giving an indication of the level of agreement between modelled and measured concentrations. This analysis suggests that the main sources of lead are emissions from industrial emissions and re-suspension processes, and contributions from long range transport primary.

Figure 11.19 - Annual mean Pb source apportionment at monitoring sites in 2021.

12 Benzo(a)pyrene

12.1 Introduction

12.1.1 Target values

A single target value (TV) for ambient concentrations of benzo(a)pyrene (B(a)P) is set out in AQSR (legislation.gov.uk, 2010). The regulations states that all necessary measures not entailing disproportionate costs to ensure that the target value is not exceeded after 31 December 2012 should be taken. The target value is an annual mean concentration of 1 ng m⁻³.

12.1.2 Annual mean modelling

A map of annual mean B(a)P in 2021 at background locations is shown in Figure 12.2. B(a)P concentrations were modelled for 2005 by (Vincent, Bush and Coleman, 2007) to inform the UK Preliminary Assessment for AQDD4 (Bush, 2007). 2021 is the fourteenth year for which a full air quality assessment is required, and national modelling of B(a)P was undertaken to assess compliance with the target value.

The B(a)P annual mean model is calibrated based on monitoring data from the national network. Consideration has been given to the appropriate application of calibration factors in the model, and for this reason separate calibration factors have been used for the contributions from area sources in Great Britain and Northern Ireland and for coke ovens at steelworks in England and Wales. The 2021 assessment follows a similar approach to that adopted since the 2015 assessment (Brookes *et al.*, 2017), including detailed local scale modelling to improve the representation of contributions from the most dominant industrial sources for B(a)P at exceedance locations (coke ovens at steelworks in England and Wales). The calibration process is described further in Sections 12.3.2, 12.4.2 and 12.4.4.

12.1.3 Overview of the PCM model for B(a)P

Figure 12.1 shows a simplified flow diagram of the PCM model for B(a)P. A summary of the PCM model method, input, and assumptions for B(a)P is presented in Table 12.1.

Figure 12.1 - Flow diagram for PCM B(a)P model

	Number of traffic stations in calibration	n/a
Pollutant specific	Fine scale modelling	Impact of emissions from coke ovens at Scunthorpe and Port Talbot modelled at 100 m spatial resolution using local meteorological data and incorporating terrain effects for Port Talbot. A contribution from unflared coke oven bleeder releases was also included at Scunthorpe. For the areas covered by the fine scale modelling, 1 km grid cells have been classified as exceeding the TV if at least nine 100 m grid squares exceed the TV or at least one square exceeds and there is population in the 1 km grid cell containing the exceeding 100m grid squares. A concentration value was defined for each 1 km grid square from the fine scale modelling from the mean of the 100 m grid squares exceeding the TV

Heading	Component	Details
		within that 1 km grid square or the mean of all 100 m grid squares for non-exceeding grid squares within the fine scale modelling domain. An exceedance was only reported if the modelled exceedance area includes locations outside of the boundary of the industrial site.
	Calibration	<p>Separate calibration for area sources in Great Britain (20 background stations across Great Britain) and Northern Ireland (23 background stations across the UK).</p> <p>Separate calibration for contributions from coke ovens (local calibration using data from 2 stations in Scunthorpe and 1 station in Port Talbot with concentrations being modelled at 100 m resolution)</p>

12.1.4 Outline of the annual mean model for B(a)P

The 1 km x 1 km annual mean background B(a)P concentration map was calculated by summing the contributions from:

- Large point sources
- Small point sources
- Point sources with emissions estimates for air quality pollutants based on reported carbon emissions (ETS points)
- Coke oven sources modelled at 100m spatial resolution.
- Local area sources

12.1.5 Chapter structure

This chapter describes modelling work carried out for 2021 to assess compliance with the B(a)P target value described above. Emissions estimates for B(a)P are described in Section 12.2. Sections 12.3 and 12.4 describes the B(a)P modelling methods for the annual mean. The modelling results are presented in Section 12.5. Detailed local scale modelling of exceedances relating to B(a)P emissions from coke ovens at steelworks in England and Wales is described in Section 12.5.3.

12.2 Emissions

B(a)P emission estimates from the UK National Atmospheric Emissions Inventory 2020 (NAEI 2020) have been used in this study (Churchill *et al.*, 2022). Emissions projections have been provided by the NAEI (Personal communication from Ben Pearson, 2022) based on BEIS EEP 2021 energy and emissions projections (BEIS, 2022). Figure 12.3 shows UK total B(a)P emissions for 2021, with the coding described in Table 4.2.

Figure 12.3 shows that B(a)P emissions in 2021 are dominated by two main sources:

- SNAP 11: Nature
- SNAP 2: Domestic combustion

The emissions inventory provides maps of emissions on a 1 km x 1 km grid, which is likely to be too coarse to incorporate very local variations in emissions from sources such as domestic heating, where there may be considerable in-square variation due to differences in fuel use (Vincent and Tsagatakis, 2014). SNAP 11: 'Nature', refers to B(a)P emissions from combustion in the natural environment such as forest fires. Despite the relatively high emissions contribution from this source sector, the method for distribution of these emissions used in the NAEI ensures that natural combustion is spread evenly across the UK and does not unduly affect the modelled ambient concentrations in any particular area.

Figure 12.3 - Total UK B(a)P emissions for 2021 by SNAP code scaled using Covid factors from NAEI 2020

12.3 B(a)P modelling: Contributions from local area sources

12.3.1 Introduction

The 2021 area source B(a)P emissions maps have been calculated from the NAEI 2020 emissions maps following the method described in Section 4.3.5. ADMS derived dispersion kernels have been used to calculate the contribution to ambient B(a)P concentrations on a 1 km x 1 km receptor grid, from the area source emissions within a 33 km x 33 km square surrounding each receptor. Concentrations have been modelled using meteorological hourly sequential data for 2021 from the WRF numerical weather prediction modelling system, as described in Appendix 4 – WRF

meteorology. The WRF model is a next-generation numerical weather prediction system developed by the US National Centre for Atmospheric Science (NCAR)(UCAR, 2020). This method accounts for spatial variation in meteorological parameters across the UK representing local dispersion characteristics within the PCM output. Meteorological data from WRF was used to construct the dispersion kernels, as described in Appendix 5 – Dispersion kernels for the area source model.

12.3.2 Area source model calibration

Figure 12.4 shows the separate calibration of the modelled annual mean area source B(a)P contribution for locations in Great Britain and Northern Ireland applied in the 2021 assessment. The calibration coefficient for locations in Great Britain has been derived by comparing the uncalibrated modelled area source component with measured concentrations at monitoring stations in Great Britain. The calibration coefficient for locations in Northern Ireland has been derived by comparing the uncalibrated modelled area source component with measured concentrations at monitoring stations across the UK. The measured concentrations have been adjusted to represent background (non-industrial) concentrations by subtracting the uncalibrated modelled point source contribution at these locations. Those stations where the uncalibrated point source contribution was $\geq 5\%$ were excluded from the calibration hence the adjustment to the measured concentrations is minimal. To calculate the calibrated area source contribution for each grid square in the country, the modelled area source contribution was multiplied by the relevant calibration fit coefficient.

As noted, for the 2021 assessment, a separate area source calibration has been carried out for locations in Great Britain and Northern Ireland. This approach was followed on the basis that:

- There are no measured exceedances for 2021 in Northern Ireland.
- Measured and modelled concentrations do not scale consistently between monitoring stations in Great Britain, while the scaling between measured and modelled concentrations is near 1:1 for background locations in United Kingdom.
- Applying a separate calibration to domestic only for Northern Ireland based on Northern Ireland monitoring as per previous assessments (Walker *et al.*, 2011; Brookes *et al.*, 2012) would lead to over prediction.
- The Derry Brandywell and Ballymena Ballykeel monitoring stations remain influential in the 2021 area source calibration for Northern Ireland. Including all UK sites in the calibration for Northern Ireland moderates the influence of these stations on the calibration while providing model estimates close to the observed concentrations at Kilmakee Leisure Centre.

In common with previous assessments, the indication that a greater calibration coefficient is required on area source contributions (primarily domestic) in Northern Ireland compared to area sources overall for the UK suggests further improvements are needed for quantifying and mapping domestic combustion emissions in Northern Ireland.

Figure 12.4 indicates similar scatter in the area source calibration for 2021 as for 2020, 2019, 2018, 2017 and 2016. As part of the calibration process, emission caps have been applied to certain sectors; this is because the use of surrogate statistics for mapping area source emissions sometimes results in unrealistically large concentrations in some grid squares for a given sector. The emission caps applied are given in Table 12.2.

Table 12.2 - Emission caps applied to B(a)P sector grids

SNAP code	Description	Cap applied (kg/a/km ²)
SNAP 4 (production processes, excludes quarrying and construction)	Chemical industry – general, non-fuel bitumen use	0.66
SNAP 4 (production processes, excludes quarrying and construction)	Electric arc furnaces, Steel production (electric arc)	0.66

Figure 12.4 - Calibration of area source model for B(a)P

12.4 B(a)P Modelling: Contributions from large and small point sources

12.4.1 Introduction

Contributions to ground level annual mean B(a)P concentrations from large point sources (those with annual emissions greater than 0.001 tonnes, or for which emission release characteristics are known) in the NAEI 2020 have been estimated by modelling each source explicitly using the atmospheric dispersion model ADMS 5.2 and sequential meteorological data for 2021 from the WRF Model. Surface roughness varied at both the dispersion and meteorological sites depending on the area type as presented in Table A5.1. Concentrations were calculated for a 99 km x 99 km square composed of a regularly spaced 1 km x 1 km resolution receptor grid. Each receptor grid was centred on the point source.

Industrial point sources of B(a)P are either fugitive (as from coking plants) or from clearly defined stacks for other sources. The emission amount is derived either from direct measurement or by emission factors. 159 point sources from the NAEI 2020 were classified as large points sources and modelled using emissions release information retrieved from the PCM stack parameters database (described in more detail in Section 4.3.1).

The NAEI 2020 also includes point source emissions estimates derived from carbon emissions data reported under the EU-Emissions Trading Scheme (ETS) (Tsagatakis *et al.*, 2022), referred to as ETS points in this report. These derived air quality pollutant emissions are particularly uncertain and therefore in previous assessments (e.g. (Brookes *et al.*, 2017)) emissions were capped at reporting thresholds and treated as small point sources. For the 2016, 2017, 2018, 2019 and 2020 assessments (Brookes *et al.*, 2019b, 2019a, 2020, 2021; Pugsley *et al.*, 2022) the NAEI recommended treating the ETS points that have emissions greater than the large points modelling threshold as large points and not to apply a cap (Personal communication from Ben Pearson, 2022). The 2021 assessment continues this approach. Thus, based on the criteria for the treatment of large point sources described above, 109 ETS point sources were modelled as an additional set of large point sources (using the

approach described above). ETS points that were not classified as large point sources were modelled using the B(a)P small points approach.

The impact of 2 further large point sources, the emissions as the result of door leakage from the coke works at Port Talbot and Scunthorpe (which are the dominant industrial sources for B(a)P), have been modelled as line sources. The emissions from the bleeders at Scunthorpe have been modelled as point sources. The models have been run at finer spatial resolution on a regularly spaced 100 m x 100 m resolution receptor grid. The detailed local scale modelling of the 2 coke ovens is described in Section 12.4.2.

For the majority of large point sources NAEI 2020 emissions were applied with scaling using projection factors to provide emission values for 2021, as described in Section 4.3.1. For each sinter plant stack and coke oven batteries at the integrated steelworks in England and Wales, reported B(a)P emissions for the year 2021 have been acquired and applied in order to provide the best representation of contributions from the most dominant industrial sources for B(a)P at exceedance locations. The NAEI provided operator reported emissions for 2021 for the integrated steelworks at Port Talbot and Scunthorpe (Personal communication from Clare Aston, 2022).

Contributions from B(a)P point sources with less than 0.001 tonnes per year emissions and without emissions release characteristics were modelled using an area source approach. NAEI 2020 emissions for small point sources were scaled to 2021 emissions using the same source sector specific projection factors applied to the large point sources. These emissions were aggregated onto a 1 km x 1 km grid before applying an ADMS 5.2 derived dispersion kernel (for non-domestic, non-road transport) to calculate the contribution to ambient concentrations at a central receptor location from small point source emissions within a 33 km x 33 km square surrounding each receptor. The method used to generate area source dispersion kernels is described in Appendix 5 – Dispersion kernels for the area source model.

12.4.2 Coke oven door sources

Detailed dispersion modelling was undertaken to derive contributions from BaP emissions from the coke ovens in England and Wales. Each source was modelled explicitly using the atmospheric dispersion model ADMS 5.2. Hourly sequential meteorological data for 2021 from WRF was used. Surface roughness was assumed to be 0.5 m at the dispersion site for both Scunthorpe and Port Talbot. Surface roughness was assumed to be 0.1 m and 0.5 m at the meteorological sites for Scunthorpe and Port Talbot respectively. Calm conditions were treated in the dispersion modelling using the ADMS calm module at the ADMS with minimum wind speed at 10 m of 0.3 m/s and critical wind speed of 1 m/s. Concentrations were calculated for a 15 km x 15 km area for Scunthorpe and a 23 km x 23 km area for Port Talbot both composed of regularly spaced 100 m x 100 m resolution receptor grids, centred on the coke ovens. To account for the complex terrain surrounding Port Talbot the effect of the local topography has been included in the 2021 modelling, with terrain heights based upon the OS Terrain 50 dataset.

12.4.3 Coke oven bleeder sources at Scunthorpe

Approximately 32 unflared releases from eight bleeders were reported by the operator at the Appleby coke ovens batteries at Scunthorpe during 2021. Coke ovens operate at positive pressure and flared, and unflared releases of coke oven gas can occur from these bleeders for safety reasons for short periods. These releases are in addition to the reported BaP annual emission from the normal operation of the plant.

Additional dispersion modelling was undertaken to assess the contribution of these short term releases to ambient annual average concentrations. Each release was modelled as an individual short period release of one hour duration with efflux volume flow rate equal to that recorded (i.e. raw gas volume released divided by the duration of the release), but with BaP emission rate factored by the duration of the release to ensure that the total mass released was correct. A source height of 26 m and diameter of 0.62 m was assumed for each release. The temperature of the release was assumed to be 80°C and the molecular weight and specific heat capacity of the release was calculated from the typical composition of wet raw coke oven gas. The influence of nearby buildings on dispersion was accounted for in the dispersion model's building wake module.

Flared sources were not included in the modelling as it was considered that the flaring would destroy any BaP in the release.

The atmospheric dispersion model ADMS 5.2. was used to model both hourly and annual mean concentrations. The meteorological parameters (data and surface roughness) were the same as those assumed for Scunthorpe in the modelling of coke oven sources (Section 12.4.2)

The hourly mean concentrations were used to form monthly averages, which were compared with monthly monitoring data from the Scunthorpe Town and Scunthorpe Low Santon monitoring sites. Measurement data from Scunthorpe Town showed an elevated monthly averaged concentration of 1.9 ng/m³ during February 2021. The modelled concentrations as the result of the operation of the coke ovens were calibrated using the best fits to the measured ambient concentrations at both Scunthorpe Town and Low Santon monitors. The modelled concentrations at Low Santon monitoring station were in better agreement than those of the Scunthorpe Town. However, the modelled concentrations fell short of predicting the peak at both stations.

Industry estimates of BaP concentration in raw coke oven gas range from negligible to the highly conservative assumption that all the BaP in the tar is volatilised and released in the gas.

The contribution to ambient annual mean concentrations from the coke oven bleeder releases were calculated for a 15 km x 15 km area composed of regularly spaced 100 m x 100 m resolution receptor grids, centred on the coke ovens.

12.4.4 Point source model calibration

In earlier assessments the modelled point source contribution (excluding coke ovens) has been calculated using a single calibration based upon monitoring data from the national network to obtain results consistent with measured concentrations. Since the 2016 assessment, the modelling and monitoring data at other industrial sites no longer supports application of a general point source calibration. With recent closures of dominant industrial sources of B(a)P there are only 2 industrial monitoring stations (Scunthorpe Low Santon and Port Talbot Margam) where the uncalibrated point source contribution is $\geq 50\%$ of the uncalibrated modelled concentration. Thus for 2016, 2017, 2018, 2019, 2020 and 2021, only the coke ovens contribution has been calibrated, using local monitoring data and the detailed local scale modelling of these sources (described in Section 12.4.2).

There is an element of circularity involved in the calibration of both area and point sources because the calibration process for each requires the subtraction of the other to isolate the component being calibrated. An approach to minimise interdependence of the calibrations was introduced in the 2012 assessment (Brookes *et al.*, 2013) and this was carried forward into the 2021 assessment, as follows:

- The area source component is calibrated first and as discussed in Section 12.3.2 only monitoring stations where the uncalibrated point source contribution is $< 5\%$, are included in the area source calibration. This minimises the influence of point sources on the area source calibration, since the contribution from point sources at non-industrial monitoring stations is typically very small and is guaranteed to be $< 5\%$ by this approach.
- In addition, monitoring stations where the uncalibrated point source contribution is $\geq 5\%$, but still relatively low ($< 50\%$) are excluded from the model calibration completely. Data for these stations are still included in the model verification.
- Given the two conditions above, only monitoring stations where the uncalibrated point source contribution is $\geq 50\%$ of the uncalibrated modelled concentration (area sources plus point sources) are included in the calibration of the point sources.

Since the 2016 assessment a general point source calibration is no longer applied, hence there is no potential for interdependence of the calibrations except for the locations impacted by the coke ovens. The approach remains valuable elsewhere as it ensures the monitoring stations applied in calibrations are most representative of the source sectors being calibrated.

To calibrate the coke ovens contribution, local scaling factors have been applied: (2.84 for door leakage and 6.95 for bleeders (compared to 2 and 0.3 for 2020, respectively) at Scunthorpe and 2.55 for door leakage (compared to 1.0 for 2020) at Port Talbot. Local scaling factors were adopted because a general calibration fit would otherwise lead to over or under prediction at each location. Measured concentrations at the industrial monitoring stations were adjusted by subtracting the calibrated modelled area source contribution and the uncalibrated contribution from other point sources (the sum of other large, small and ETS point source contributions, excluding the coke ovens) so that the measured value represented the coke ovens component only. The local scaling approach guarantees the modelled total B(a)P concentration provides a reasonable representation of the observed concentrations at these monitoring stations.

The contribution from the coke oven bleeder releases was included in the adjustment of the monitoring data prior to calculation of the calibration coefficient for the reported coke oven point source. The local scaling for Scunthorpe was derived from the Scunthorpe Town and Low Santon monitoring sites.

12.5 Results

12.5.1 Verification of mapped values

Figure 12.5 presents a comparison of modelled and measured annual mean B(a)P concentrations in 2021 at monitoring station locations differentiated by station classification. This figure includes lines to represent the data quality objective for modelled annual mean B(a)P concentrations: $y=x-60\%$ and $y=x+60\%$ (see Section 1.5). The results for industrial and background monitoring stations influenced by contributions from coke ovens are compared to modelled concentrations derived from the detailed local scale modelling of these sources, described in Section 12.4.2. The results for other industrial and background monitoring stations are compared to modelled concentrations derived from the national scale modelling, and therefore the model results for these stations are further differentiated in Figure 12.5.

Figure 12.5 - Verification of annual mean B(a)P across all stations

Summary statistics for modelled and measured B(a)P concentrations are listed in Table 12.3, including the percentage of stations at which modelled concentrations are outside of the data quality objectives (DQOs), and the total number of stations included in the analysis. Summary statistics for industrial and background monitoring stations influenced by contributions from coke ovens derived from the detailed local scale modelling of the coke ovens have been indicated. Summary statistics from the national modelling have been calculated for industrial and urban background stations not influenced by coke ovens, and rural stations.

The mean measured and modelled concentrations are in reasonable agreement for all monitoring stations, except those industrial stations not influenced by contributions from coke ovens for which the dominant local industrial sources are no longer operating. The agreement between measured and modelled concentrations at industrial stations influenced by contributions from coke ovens is naturally better since for two of these three stations the model has been scaled to reproduce the observed concentrations. The R^2 value across all stations is generally better than that for individual station classes reflecting that overall, the model is capturing the variation in observed concentrations. R^2 is less meaningful for the individual station classes, in particular where the number of stations is low,

however it does indicate that for background stations that are primarily expected to be influenced by domestic emissions, the model captures a reasonable proportion of the observed variation in concentrations. The low concentrations at rural stations are captured by the modelling.

Table 12.3 - Summary statistics for comparison between modelled and measured annual mean B(a)P concentrations at different monitoring stations, 2021

	Mean of measurements (ng/m ³)	Mean of model estimates (ng/m ³)	R ²	% of stations outside DQO of $\pm 60\%$	Number of stations in assessment
Industrial stations (not influenced by coke ovens)	0.24	0.12	0.19	50%	4
Industrial stations (coke oven influenced)	0.58	0.43	0.99	33%	3
Background stations (not influenced by coke ovens)	0.18	0.13	0.46	13%	23
Background stations (coke oven influenced)	0.31	0.32	-	0%	1
Rural stations	0.11	0.04	0.79	33%	6
All	0.51	0.16	0.48	26%	31

12.5.2 Source apportionment

A source apportionment graph is plotted in Figure 12.6 to present the B(a)P contribution from different sources at monitoring station locations. It should be noted that for industrial and background stations in the areas covered by the fine scale modelling of the coke ovens (Scunthorpe Town, Scunthorpe Low Santon, Port Talbot Margam, Swansea Cwm Level Park), described in Section 12.4.2, the modelled source apportionment includes the local modelling. The source apportionment for stations outside these areas is from the national scale modelling. Measured concentrations at the stations are also presented, giving an indication of the level of agreement between modelled and measured concentrations. Domestic combustion, at many stations, and industry, at industrial stations, are the most important sources. The contributions from other sources are much smaller.

Figure 12.6 - Annual mean B(a)P source apportionment at background national network monitoring stations in 2021 (the area type of each station is shown in parenthesis after its name)

12.5.3 Detailed comparison of modelling results with the target value

Results of the assessment in terms of comparisons of the modelled concentrations with the TV have been reported in e-Reporting Data flow G (*UK-Air*, 2022). For the areas covered by the fine scale modelling, 1 km grid cells have been classified as exceeding the TV if at least nine 100 m grid squares exceed the TV or at least one 100 m square exceeds and there is population in the exceeding 1 km grid square. A concentration value was defined for each 1 km grid square from the fine scale modelling from the mean of the 100 m grid squares exceeding the TV within that 1 km grid square or the mean of all 100 m grid squares for non-exceeding grid squares within the fine scale modelling domain.

Exceedances of the 1 ng m^{-3} TV have been modelled for two zones (South Wales and Swansea Urban Area) for 2021. The following information is based on a source apportionment assessment including the fine scale modelling.

No exceedance of the TV has been modelled in the Yorkshire & Humberside zone for 2021. As the elevated ground level concentrations of BaP, from the Appleby coke ovens of the Scunthorpe steelworks, are confined to the boundary of the site.

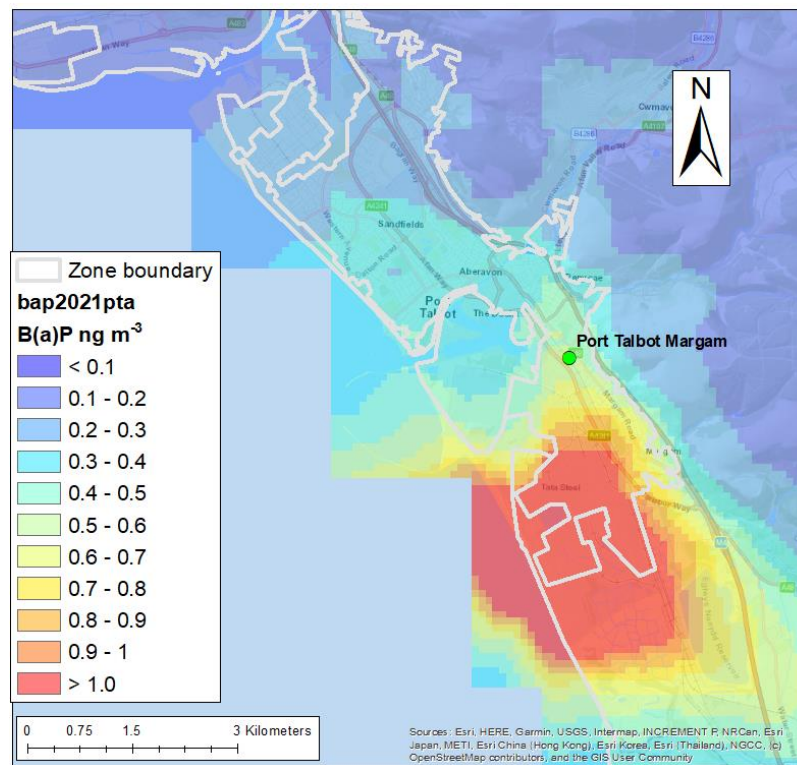

Exceedances in 6 km^2 of the South Wales zone and 3 km^2 of the Swansea Urban Area have been modelled, associated with industrial emissions from the coke oven at the steel plant at Port Talbot.

Figure 12.7 and Figure 12.8 show the modelled annual mean B(a)P concentration at a $100 \text{ m} \times 100 \text{ m}$ spatial resolution in the vicinity of the coke ovens at Scunthorpe and Port Talbot respectively. Figure 12.9 shows the complex terrain surrounding Port Talbot which has been incorporated into the 2021 modelling and influences the dispersion of emissions from the coke ovens in this location.

13 Acknowledgements

This work was funded by the UK Department for Environment, Food and Rural Affairs, The Welsh Government, The Scottish Government and The Department of the Environment for Northern Ireland.

The authors would also like to thank: Hanson Building Products Limited for providing SO₂ measurements and INEOS for providing benzene measurements.

Detailed information and measurements for the Pontardawe Leisure Centre monitoring site was kindly provided by Neath Port Talbot County Borough Council. This monitoring site was included in the analysis for verification of the local scale modelling of Ni concentrations in Pontardawe. The authors would also like to thank the Natural Resources Wales, local authorities and plant operators for helping with the nickel emission data and release characteristics for specific plants.

The authors would like to thank providers of model input data that supported local scale modelling of B(a)P concentrations in the vicinity of the steelworks at Port Talbot and Scunthorpe. Detailed B(a)P emission data for Port Talbot and Scunthorpe were provided by the NAEI and plant operators.

Appendices

Appendix 1 - Monitoring sites used to verify the mapped estimates

Appendix 2 - Monitoring sites for As, Cd, Ni, Pb and B(a)P

Appendix 3 – Small point source model

Appendix 4 – WRF meteorology

Appendix 5 – Dispersion kernels for the area source model

Appendix 6 – Method for calculating and mapping emissions from aircraft and shipping

Appendix 7 – Monitoring stations used in PM_{2.5} AEI calculation

Appendix 8 – The PCM Roads Kernel Model

Appendix 9 – Selected acronyms

Appendix 1 - Monitoring sites used to verify the mapped estimates

Table A1.1 lists the air quality monitoring network names for the sites used to verify the 2021 model output of the pollutants, which are given in Table A1.2. Table A1.2 also lists additional monitoring sites, operated by Hanson Building Products Ltd., which are used to verify the SO₂ models, and INEOS, which are used to verify the benzene modelling.

Appendix 2 - Monitoring sites for As, Cd, Ni, Pb and B(a)P

The monitoring stations operating during 2021 for the purpose of AQSR reporting have been listed within e-Reporting Data flow C (Assessment Regimes), which can be found on UK-Air (*UK-Air*, 2022). A summary of the annual mean As, Cd, Ni, Pb and B(a)P measurements used for calibrating and verifying the modelling used in the assessment are provided here.

Heavy Metal Monitoring sites

2021 annual mean concentrations of As, Cd, Ni and Pb are presented in Table A2. 1 for heavy metal monitoring sites where data capture was at least 75%. The mass concentrations presented are rounded to two significant figures.

Table A2. 1 – Summary of urban and rural heavy metal mass concentrations, 2021

Appendix 3 – Small point source model

Introduction

Small industrial sources were generally represented in early maps (Stedman, Bush and Vincent, 2002) as 1 km square volume sources. However, this approach in some cases lead to unreasonably high concentrations close to the source. A revised small point source model was developed that uses dispersion kernels that take these factors into account.

The dispersion model ADMS 3.0 was used to prepare the dispersion kernels.

Discharge Conditions

The National Atmospheric Emission Inventory (NAEI) contains limited information concerning the discharge characteristics of individual emission sources. In many cases the information is limited to data on the total annual emission of individual pollutants. It is therefore necessary to make some general assumptions concerning the discharge height, the discharge temperature, the volumetric flow rate of the discharge and the discharge velocity. The approach adopted has been to make reasonable, but generally conservative assumptions corresponding to industrial practice.

Sulphur dioxide

For sulphur dioxide, it was assumed that the plant operates continuously throughout the year. The stack height was estimated using the following equations taken from the 3rd edition of the Chimney Heights Memorandum:

If the sulphur dioxide emission rate, R_A kg/h, is less than 10 kg/h, the chimney height, U m, is given by:

$$U = 6R_A^{0.5},$$

If R_A is in the range 10-100 kg/h:

$$U = 12R_A^{0.2},$$

Emission rates in excess of 100 kg/h were not considered in this study.

No account was taken of the effects of buildings: it was assumed that the increase in chimney height to take account of building effects provided by the Memorandum would compensate for the building effects.

It was then assumed that the sulphur dioxide concentration in the discharge would be at the limit for indigenous coal and liquid fuel for new and existing plant provided by Secretary of States Guidance-Boilers and Furnaces, 20-50 MW net rated thermal input PG1/3(95). The limit is 3000 mg m⁻³ at reference conditions of 273 K, 101.3 kPa, 6% oxygen for solid fuel firing and 3% oxygen for liquid firing and dry gas. It was assumed that the oxygen content in the discharge corresponds with the reference condition. The moisture content of the discharge was ignored. It was assumed that the temperature of discharge was 373 K: higher temperatures would lead to improved buoyancy and hence lower ground level concentrations while lower temperatures usually result in unacceptable water condensation. A discharge velocity of 10 m/s was selected to be representative of most combustion source discharges. The discharge diameter d m was calculated from:

$$d = \sqrt{\frac{4qT}{273\pi cv}},$$

where: q is the sulphur dioxide emission rate, g s⁻¹

T is the discharge temperature, 373 K

c is the emission concentration at reference conditions, 3 g m⁻³

v is the discharge velocity, 10 m s⁻¹

Table A3.1 shows the modelled stack heights and diameters.

Table A3.1 - Modelled stack heights and diameters for sulphur dioxide

Emission rate			Stack height, m	Stack diameter, m
g s ⁻¹	kg h ⁻¹	t a ⁻¹		
0.1	0.36	3.2	3.60	0.08
0.2	0.72	6.3	5.09	0.11
0.5	1.8	15.8	8.05	0.17
1	3.6	31.5	11.38	0.24
2	7.2	63.1	16.10	0.34
5	18	157.7	21.39	0.54
10	36	315.4	24.57	0.76
20	72	630.7	28.23	1.08

Oxides of nitrogen

For nitrogen dioxide, it was assumed that the plant operates continuously throughout the year. The stack height was estimated using the following equation taken from the 3rd edition of the Chimney Heights Memorandum for very low sulphur fuels:

$$U = 1.36Q^{0.6}(1 - 4.7 \times 10^{-5}Q^{1.69}),$$

where: Q is the gross heat input in MW.

This relationship applies for heat inputs up to 150 MW. For larger heat inputs a fixed height of 30 m was used corresponding to an approximate lower limit derived from available data on stack heights for large sources.

The gross heat input used in the above equation was calculated from the oxides of nitrogen emission rate using an emission factor of 10600 kg/MTh (0.100 g/MJ) for oxides of nitrogen emitted from natural gas combustion in non-domestic non-power station sources taken from the NAEI.

For fuels containing significant sulphur, the actual stack height will be greater to allow for the dispersion of sulphur dioxide so that the approach taken is expected to lead to an overestimate of ground level concentrations.

The emission limits for oxides of nitrogen provided by Secretary of States Guidance-Boilers and Furnaces, 20-50 MW net rated thermal input PG1/3(95) depend on the type of fuel and are in the range 140-650 mg m⁻³ at reference conditions. A value of 300 mg m⁻³ was used in the calculation of the stack discharge diameter. Other assumptions concerning discharge conditions followed those made for sulphur dioxide above. Table A3.2 shows the modelled stack heights and diameters.

Table A3.2 - Modelled stack heights and diameters for oxides of nitrogen

Emission rate		Stack height, m	Stack diameter, m
g s ⁻¹	t a ⁻¹		
0.1	3.2	1.36	0.24
0.2	6.3	2.06	0.34
0.5	15.8	3.57	0.54
1	31.5	5.40	0.76
2	63.1	8.15	1.08
5	157.7	13.72	1.70
10	315.4	19.12	2.41
20	630.7	21.34	3.41
50	1576.8	30.00	5.38
100	3153.6	30.00	7.61

Particulate matter, PM₁₀

The stack heights and diameters used for oxides of nitrogen were also used to provide the kernels for particulate matter PM₁₀. This will provide a conservative assessment of PM₁₀ concentrations for the

following reasons. The emission limits for total particulate matter provided by Secretary of States Guidance-Boilers and Furnaces, 20-50 MW net rated thermal input PG1/3(95) depend on the type of fuel and are in the range 5-300 mg m⁻³ at reference conditions. The emission limit for total particulate matter includes but is not limited to the contribution from PM₁₀.

Dispersion Modelling

The dispersion model ADMS 3.0 was used to predict ground level concentrations on two receptor grids:

- an “in-square” grid covering an area 1 km x 1 km with the source at the centre and with receptors at 33.3 m intervals;
- an “outer-grid” covering an area 30 km x 30 km with the source at the centre and with receptors at 1 km intervals.

A surface roughness value of 0.5 m was used, corresponding to areas of open suburbia.

Meteorological data for Heathrow for the years 1993-2002 was used in the assessment, with most model runs using the 2000 data.

Results

Sulphur dioxide

Table A3.3 shows the predicted “in-square average” concentration for the 1 km square centred on the emission source for 2000 meteorological data.

Table A3.3 - Predicted in-square concentration, for sulphur dioxide

Emission rate, g s ⁻¹	Average in square concentration, µg m ⁻³
0.1	0.599
0.2	0.934
0.5	1.555
1	2.19
2	2.92
5	4.57
10	6.56
20	8.86

The results shown in Table A3.3 may be approximated by the relationship

$$C = Aq^{0.5},$$

where: C is the in-square concentration, µg m⁻³ and q is the emission rate, g s⁻¹. A is a proportionality factor (2.07 in 2000).

Table A3.4 shows the predicted in-square concentration for an emission rate of 10 g s⁻¹ for meteorological years 1993-2002. Table A3.4 also shows the inter-annual variation in the factor A.

Table A3.4 - In-square concentrations for 10 g/s emissions

Year	In-square concentration, $\mu\text{g m}^{-3}$	Factor A
1993	6.21	1.96
1994	6.01	1.90
1995	6.12	1.94
1996	6.23	1.97
1997	6.10	1.93
1998	6.18	1.95
1999	6.49	2.05
2000	6.56	2.07
2001	6.32	2.00
2002	6.51	2.06

Figure A3.1 shows the predicted “outer-grid” concentration along the east-west axis through the source for 2000 meteorological data for a range of rates of emission (in g/s). Figure A3.1 does not include results for the 1 km source square.

Figure A3.1 - Sulphur dioxide concentration on east-west axis, 2000 meteorological data

Figure A3.2 shows the same model results plotted as $C/q^{2/3}$. The spread of the model results is greatly reduced so that as a reasonable approximation all the model results may be reduced to a single line.

Figure A3.2 - Reduced sulphur dioxide concentrations on the east-west axis, 2000 meteorological data

Thus, it is proposed to use the results for an emission rate of 10 g/s for all emission rates in the range 0.1-20 g/s in the preparation of dispersion kernels for industrial sulphur dioxide emissions. The dispersion kernel will be multiplied by $10 \cdot (q/10)^{2/3}$ to provide estimates of the impact of emission q (g s^{-1}) at each receptor location. Separate kernels have been created from each meteorological data year 1993-2002.

Oxides of nitrogen

Table A3.5 shows the predicted “in-square average” concentration for the 1 km square centred on the emission source for 2000 meteorological data.

Table A3.5 - In-square oxides of nitrogen concentrations, 2000

Emission rate, g s^{-1}	In square concentration, $\mu\text{g m}^{-3}$
0.1	0.464
0.2	0.764
0.5	1.37
1	1.97
2	2.6
5	3.31
10	3.58
20	4.34
50	3.745
100	4.3

The results shown in Table A3.5 may be approximated in the range 0.1-20 g s^{-1} by the relationship

$$C = B \log_{10}(10q) + 0.464,$$

where: C is the in-square concentration, $\mu\text{g m}^{-3}$ and q is the emission rate, g s^{-1} . and B is a numerical constant, 1.68 in 2000.

For emission rates in the range 20-100 g s^{-1} , the in-square concentration is approximately 4 $\mu\text{g m}^{-3}$.

Table A3.6 shows the predicted in-square concentration for an emission rate of 20 g s^{-1} for meteorological years 1993-2002. Table A3.6 also shows the inter-annual variation in the factor B.

Table A3.6 - Inter annual variation in in-square oxides of nitrogen concentration

Year	In-square concentration, $\mu\text{g m}^{-3}$	Factor B
1993	3.62	1.37
1994	3.88	1.48
1995	3.74	1.42
1996	4.3	1.67
1997	3.66	1.39
1998	3.64	1.38
1999	4.14	1.60
2000	4.34	1.68
2001	4.02	1.55
2002	4.68	1.83

Figure A3.3 shows the predicted “outer-grid” oxides of nitrogen concentration along the east-west axis through the source for a range of rates of emission (in g s^{-1}).

Figure A3.3 - Oxides of nitrogen concentration on east-west axis, 2000 meteorological data

Figure A3.4 shows the same model results plotted as $C/q^{0.6}$. The spread of the model results is greatly reduced so that as a reasonable approximation all the model results may be reduced to a single line.

Figure A3.4 - Reduced oxides of nitrogen concentrations on the east-west axis, 2000 meteorological data

Thus, it is proposed to use the results for an emission rate of 20 g s^{-1} for all emission rates in the range $0.1\text{--}100 \text{ g s}^{-1}$ in the preparation of dispersion kernels for oxides of nitrogen emissions. The dispersion kernel will be multiplied by $20 \cdot (q/20)^{0.6}$ to provide estimates of the impact of emission $q \text{ g s}^{-1}$ at each receptor location. Separate kernels have been created for each meteorological data year 1993–2002.

Method

Sulphur dioxide

Point sources with emissions greater than or equal to 500 tonnes per year (15.85 g s^{-1}) have been modelled explicitly using ADMS. Point sources with emissions less than 500 tonnes per year have been modelled using the small points model. This model has two components.

The in-square concentration for each source has been calculated using the following function:

$$C = 1.98 \cdot q^{0.5}$$

where C is the in-square concentration, $\mu\text{g m}^{-3}$ and q is the emission rate, g s^{-1} and 1.98 is a numerical constant, calculated as the average value over the years 1993–2002 for met data at Heathrow.

The outer-grid concentration has been calculated by adjusting the emissions for each source using the function:

$$Q = 10 \cdot (q/10)^{0.667},$$

where: q is the emission rate, g s^{-1} and Q is the adjusted emissions. The sum of the adjusted emission was then calculated for each grid square and the outer-grid concentration calculated using a small points dispersion kernel (which was calculated as the average over the years 1993–2002 for met data at Heathrow).

The in-square and outer-grid concentrations were then summed to calculate the total contribution to ambient annual mean concentrations from these small point sources.

Oxides of nitrogen

Point sources with emissions greater than or equal to 500 tonnes per year (15.85 g s^{-1}) have been modelled explicitly using ADMS. Point sources with emissions less than 500 tonnes per year have been modelled using the small points model. This model has two components.

The in-square concentration for each source has been calculated using the following function:

$$C = 1.54 \cdot \log_{10}(10q) + 0.464,$$

where: C is the in-square concentration, $\mu\text{g m}^{-3}$ and q is the emission rate, g s^{-1} and 1.54 is a numerical constant, calculated as the average value over the years 1993-2002 for met data at Heathrow.

The outer-grid concentration has been calculated by adjusting the emissions for each source using the function:

$$Q = 20 \cdot (q/20)^{0.6},$$

where: q is the emission rate, g s^{-1} and Q is the adjusted emissions. The sum of the adjusted emission was then calculated for each grid square and the outer-grid concentration calculated using a small points dispersion kernel (which was calculated as the average over the years 1993-2002 for met data at Heathrow).

The in-square and outer-grid concentrations were then summed to calculate the total contribution to ambient annual mean concentrations from these small point sources.

PM₁₀ and PM_{2.5}

The method for PM₁₀ and PM_{2.5} was the same as for NO_x, except that point sources with emissions greater than or equal to 200 tonnes per year (6.34 g s^{-1}) have been modelled explicitly using ADMS. Point sources with emissions less than 200 tonnes per year have been modelled using the small points model.

Benzene

The method for benzene was different. Point sources with combustion emissions greater than or equal to 5 tonnes per year (0.16 g s^{-1}) have been modelled explicitly using ADMS. Fugitive and process point sources have been modelled using a different small points model, as described in Section 8.3.2.

Appendix 4 – WRF meteorology

The meteorological input data for the PCM model for the 2021 compliance assessment was 50 km by 50 km gridded outputs from the Weather Research and Forecasting (WRF) numerical weather prediction modelling system (<https://www.mmm.ucar.edu/weather-research-and-forecasting-model>). Table A4.1 gives the options used in the WRF calculations. The WRF outputs were used in the point source modelling (detailed in Section 4.3.1, the area source model (see Appendix 5 – Dispersion kernels for the area source model) and the roads kernel model (see Appendix 8 – The PCM Roads Kernel Model). WRF meteorological data was used for the first time for the 2020 assessment.

Table A4.1 - Settings applied to WRF simulations

Parameters	Setting applied
WRF version	3.5.1
Grid resolution (domain)	50 km (Europe)
Spatial projection	ETRS89 Lambert Conformal Conic
Initial and lateral boundary conditions	Global Forecast System (GFS), 0.5 degree (GFS Forecast, 2021)
Land use	US Geological Survey land use types
Vertical layers	23
Nudging	Grid analysis nudging (U, V, Q and T), 3h nudging time interval throughout a simulation period, and nudging within PBL and above
Radiation (SW/LW)	RRTM/Dudhia
Cumulus	Kain-Fritsch
Microphysics	WSM 3
PBL	ACM2 (Pleim, 2007)
Land surface	5-layer thermal diffusion (Pleim, 2006)
Surface layer	P-X (Pleim, 2006)
Time resolution	Adaptive time step, hourly output
Year modelled	2021

Appendix 5 – Dispersion kernels for the area source model

Dispersion kernels for calculating the annual mean contribution of emissions from area sources to ambient annual mean concentrations were calculated using ADMS 5.2. Separate kernels were calculated for traffic, domestic and other area sources (which were assumed to have a constant temporal profile of emissions). Kernels were generated for the assessment year using hourly sequential meteorological data from the WRF model (see Appendix 4 – WRF meteorology). The dispersion parameters used to calculate the kernels are listed in Table A5.1. The emission profiles used to represent traffic emissions for the traffic kernels are shown in Figure A5.1a and Figure A5.1b. These profiles result from developments for the 2015 assessment modelling to update the temporal profiles for road traffic. The profiles by month of the year, hour of the day and day of the week were obtained from DfT traffic flow data for all traffic in Great Britain averaged over the period 2010-2014 (DfT, 2022a).

Figure A5.1a - Normalised hourly and daily temporal profiles of traffic emissions

Figure A5.1b - Normalised monthly profile of traffic emissions⁹

⁹ A 2021 specific monthly profile was used for 2021 in preference to the long term average in order to account for the timing of covid-19 lockdowns.

A time varying emissions profile was applied for domestic sources the first time in the 2011 assessment to better represent emissions related to domestic combustion. The 2011 – 2019 assessments used a time varying emissions profile calculated for the Waddington meteorological station. The 2020 and 2021 assessments used meteorological data from the WRF model (see Appendix 4 – WRF meteorology) and hence regional time varying emissions profiles have been applied in this work. Both seasonal and diurnal profiles have been used to weight domestic emissions. These weightings have been developed and applied following a similar method to (Coleman *et al.*, 2001). In this work a normalised diurnal profile has been superimposed onto a seasonal profile based on degree days calculated from temperature data for each WRF grid cell and the assessment year. The diurnal profile applied has been estimated from (Coleman *et al.*, 2001), see Figure A5.2. Degree days provide a simple but effective tool to relate energy use and emissions from buildings to the weather (Day, 2006). A degree day is a unit used to determine the heating requirements of buildings, representing a fall of one degree below a specified average outdoor temperature (15.5 °C, in this case). Degree days for each WRF grid cell have been calculated from the equation:

$$D_d = \frac{\sum_{i=1}^N \theta_b - \theta_{o,i}(\theta_b - \theta_{o,i} \geq 0)}{N}$$

Where D_d is the daily degree days for one day, θ_b is the base temperature, $\theta_{o,i}$ is the ambient (or outdoor) air temperature and N is the number of hours of available data in a given day. Figure A5.3 shows an example seasonal profile of degree days calculated for one WRF grid cell in London for the year 2020. The seasonal profile of degree days has been verified versus National Grid, National Transmission System gas demand data.

Figure A5.2 - Diurnal profile of domestic emissions estimated from (Coleman *et al.*, 2001)

Figure A5.3 - Seasonal profile of degree days calculated for an example WRF grid cell in London in 2021 (base temperature of 15.5°C)

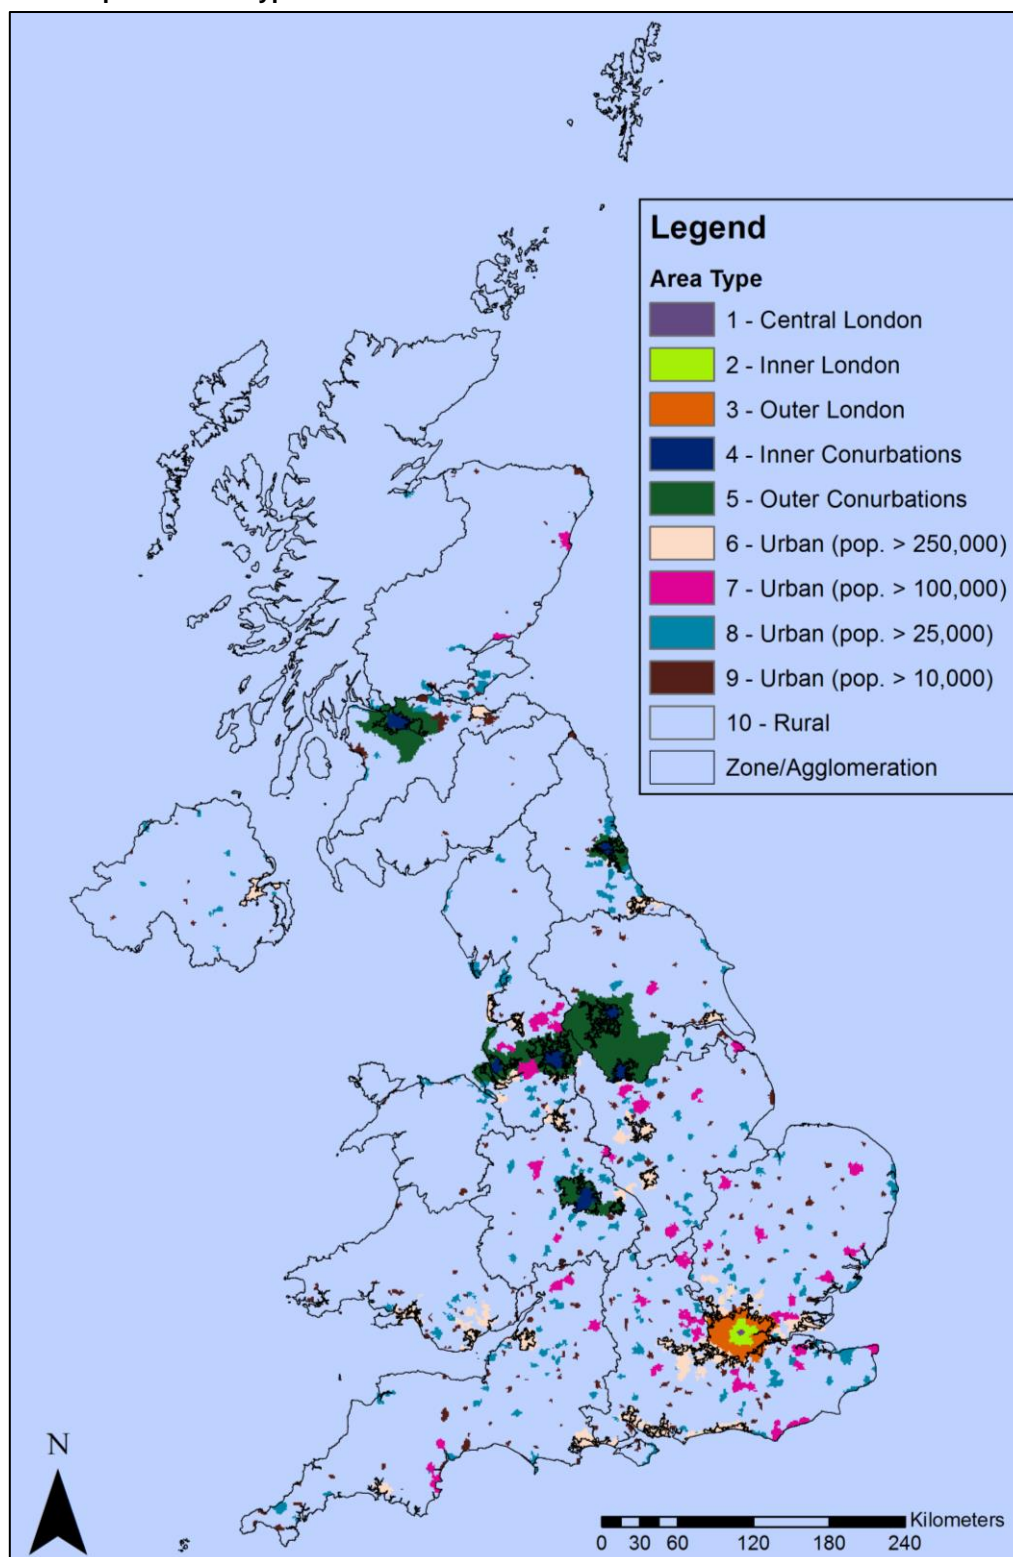

For SO₂, NO_x, NO₂, PM₁₀, PM_{2.5}, C₆H₆, heavy metals (Pb, As, Cd, Ni) and B(a)P the area source dispersion kernels are on a 1 km x 1 km resolution matrix and are made using ADMS 5.2. The centre squares have been scaled to remove the impact of sources within 50 m of the receptor location in that square on the basis that background sites are not located very close to specific sources such as major roads. Different kernels have been made for different area types, to take into account different dispersion conditions in urban areas of different sizes. The kernels have been made specific to different types of location by varying minimum Monin Obukhov Length (LMO) and surface roughness due to different land use (see Table A5.1). The location of the different area types are shown in Figure A5.4.

Table A5.1 - Summary of inverted dispersion kernel parameters

Kernel name	Area types	Type of location	Minimum Monin-Obukhov length (m)		Surface roughness (m)		Height (m) of volume source	Variable emission profile?	Emission rate (g m ⁻³ s ⁻¹)
			Disp. site	Met. site	Disp. site	Met. site			
Non-road transport	1,2,4	Conurbation	25	Varies by predominant area type of WRF grid cell	1.0	Varies by WRF grid cell based on USGS Land Use	30	N	3.33E-08
Non-road transport	3,4,5,6,7,8	Smaller urban	20	Varies by predominant area type of WRF grid cell	0.5	Varies by WRF grid cell based on USGS Land Use	30	N	3.33E-08
Non-road transport	9,10	Rural	10	Varies by predominant area type of WRF grid cell	0.1	Varies by WRF grid cell based on USGS Land Use	30	N	3.33E-08
Domestic	1,2,4	Conurbation	25	Varies by predominant area type of WRF grid cell	1.0	Varies by WRF grid cell based on USGS Land Use	20	Y	5.0E-08
Domestic	3,4,5,6,7,8	Smaller urban	20	Varies by predominant area type of WRF grid cell	0.5	Varies by WRF grid cell based on USGS Land Use	20	Y	5.0E-08
Domestic	9,10	Rural	10	Varies by predominant area type of WRF grid cell	0.1	Varies by WRF grid cell based on USGS Land Use	20	Y	5.0E-08
Road transport	1,2,4	Conurbation	25	Varies by predominant area type of WRF grid cell	1.0	Varies by WRF grid cell based on USGS Land Use	10	Y	1.0E-7
Road transport	3,4,5,6,7,8	Smaller urban	20	Varies by predominant area type of WRF grid cell	0.5	Varies by WRF grid cell based on USGS Land Use	10	Y	1.0E-7
Road transport	9,10	Rural	10	Varies by predominant area type of WRF grid cell	0.1	Varies by WRF grid cell based on USGS Land Use	10	Y	1.0E-7

The dispersion kernels used for fugitive and process point sources of benzene are the same as the non-road transport kernels but with the values for the central receptor location calculated as described in Section 8.3.2.

Appendix 6 – Method for calculating and mapping emissions from aircraft and shipping

Aircraft

Aircraft emissions were calculated using data obtained from the NAEI (Churchill *et al.*, 2022) for emissions from planes in various phases of flying (e.g. take off, landing, taxiing). The NAEI provides estimates of total emissions for aircraft, which include emissions up to a height of 1000 m. Ground level emissions for use in PCM modelling were calculated on the basis of:

$$\text{Ground level emissions} = \text{Taxi out} + \text{Hold} + \text{Taxi in} + \text{APU arrival} + \text{APU departure} + (0.5 \times \text{Take off}) + (0.5 \times \text{Landing}) + (0.5 \times \text{Reverse thrust}).$$

The factor of 0.5 has been chosen on the basis of findings from detailed studies (Underwood, 2009). Initial climb, climb-out and approach are included in the emission inventory but excluded from ground level emissions used for the PCM model.

Figure A6.1 and Figure A6.2 show good agreement between the measured and modelled annual mean ground-level NO_x concentrations at monitoring sites in the vicinity of Heathrow and Gatwick airports for 2008, respectively, based on this approach.

Figure A6.1 - Comparison of the measured and modelled annual mean NO_x at Heathrow Airport for 2008

Figure A6.2 - Comparison of the measured and modelled annual mean NO_x at Gatwick Airport for 2008

Shipping

A revised, more sophisticated, method has been used to map UK shipping emissions for the NAEI 2016, NAEI 2017, NAEI 2018, NAEI 2019 and NAEI 2020. Previously, shipping emissions were estimated by modelling fuel consumption from a database of shipping activities around UK waters for different vessel, fuel and journey types (Entec, 2010). This approach provided the best available solution at that time but had some recognised issues such as the age of the dataset (dating from 2007), estimated location of vessels rather than actual locations, low spatial resolution compared with other NAEI outputs¹⁰ and insufficient representation of shipping types other than internationally trading vessels. Improvements made to the shipping emissions modelling for the NAEI National Inventory reporting, which were first reported in (Scarborough *et al.*, 2017), provides higher resolution and greater accuracy to shipping emissions estimates (through improved coverage of various vessel types), as well as enabling a deeper understanding of the spatial pattern of emissions compared with the previous approach.

The revised method has been developed using Automatic Identification System (AIS) data supplied by the Maritime and Coastguard Agency. AIS is an on-board ship system that transmits a message containing a vessel's position - and other information such as speed - every few seconds, to be received by other vessels, onshore or by satellites¹¹. A complete set of one year's worth of AIS data received by terrestrial UK receivers was obtained and processed to give a dataset that records shipping activity at five-minute intervals for the whole of the year 2014. This was then used to calculate fuel consumption and emissions for each vessel for the year 2014 in conjunction with a second dataset of technical characteristics of individual vessels. The estimates for year 2014 were then forecast to the current NAEI year accounting for activity changes over time, the 2015 sulphur emission control area change in sulphur content limit, fleet-wide efficiency gains and additional NO_x emission factor changes to account for fleet turnover. A detailed discussion of the methodology used to develop a shipping emissions inventory from AIS data can be found in (Scarborough *et al.*, 2017).

The process of inventory mapping seeks to spatially disaggregate NAEI inventory totals in a way that represents how those emissions are geographically distributed in the real world. AIS data are inherently spatial as they record a vessel's position, and so emissions from each ship can be easily attributed to the NAEI 1 km grid using the longitude and latitude accompanying each AIS message. A small number of messages are erroneously located upon terrestrial grid squares (Scarborough *et al.*, 2017, p. 10) or are legitimately in non-UK water bodies within the NAEI mapping area (e.g. vessel movements within major rivers in north-eastern France). These emissions should not exist within the UK shipping map and have been removed.

Emissions caps applied for the shipping sector for 2021 were consistent with those applied in previous years. The NAEI shipping inventory improvements have resulted in a significantly lower impact of these caps, resulting in an emissions loss of around 1% compared with 5% before the inventory improvement as a result of being more realistically distributed.

¹⁰ NAEI maps are drawn on 1x1km resolution grid, but pre-2016 shipping emissions were based on 5x5km gridded emissions and the NAEI inherited this lower resolution limit.

Appendix 7 – Monitoring stations used in PM_{2.5} AEI calculation

Table A7.1 lists the Eol codes, air quality monitoring station names, the station classification and instrument type for the sites used for the PM_{2.5} AEI calculation in the 2021. The instruments that were used in the 2021 assessment were:

- Ref.eq - Reference equivalent converted from raw FIDAS
- TEOM FDMS - Tapered Element Oscillating Microbalance Filter Dynamic Measurement System
- BAM - Beta Attenuation Monitoring
- Mixed – instrument change part way through the year (in most cases from TEOM FDMS to Ref. eq)

Appendix 8 – The PCM Roads Kernel Model

Description of the model

The PCM Roads Kernel Model (PCM-RKM) has been set up to calculate roadside concentrations of NO₂, NO_x, PM₁₀, PM_{2.5} and benzene on urban major roads. The model uses the ADMS-Roads dispersion model¹² (Version 5.0). Individual model runs are carried out for the approximately 9000 census points covering UK urban major roads. Each model run is parameterised using specific input data for the census point. These inputs are as follows and are described below:

- Road geometry
- Traffic speeds, emissions and traffic counts
- Meteorology
- Receptor locations

Road geometry

The PCM model uses a line coverage¹³ to represent the layout of UK major roads, in combination with the census point dataset which describes the traffic flows on these roads. There is one census point per major road between junctions with other major roads. The traffic flow between major road junctions is assumed to be constant based on the assumption that the majority of traffic joins or leaves major roads at junctions with other major roads.

An assessment of variation in modelled concentrations with road orientation (not detailed here) suggests that differences in road orientation can make an approximately +/- 40% change for a receptor at 4 m from the roadside. This assessment evaluated the relative change in concentration modelled for receptors at various distances from the road for all road links. For each census point, the concentration modelled for a receptor at a particular distance from the roadside was compared to the concentration modelled for an identical road link aligned due north at the same distance from the road. The relative change is largely independent of road type, traffic flow and road width; hence the orientation of a particular road is important to the modelled concentration that results. This difference is driven by the orientation of the road relative to the prevailing wind direction.

The orientation of roads within the PCM model can be described at three levels. The coarsest level is the census point level where multiple UK major road sections are associated with each census point. This level of detail corresponds to the end nodes of the road links. The major road sections level data set, which comes from Ordnance Survey data, contains major road links but has nodes at junctions with both major roads and minor roads. Finally, there is the x, y coordinate level, where the coordinates of each arc of every link which makes up the major roads GIS dataset are available, therefore several grid references correspond to each link.

The number of road links for each census point means that the stretches of road are too long to be accurately described by one orientation calculated from the end nodes of the full length of road. To best represent the road orientation the x, y coordinate level would be most accurate. However, this would produce approximately 40 records for each census point, and it would be unfeasible to resolve variations in roadside concentrations down to this level when the underlying traffic data is represented at a much coarser level. Hence to represent the orientation of road links associated with each census point the end nodes of the major road sections have been used to calculate the bearing of the road link with respect to due north. The nearest UK major road section associated with the census point is used to define the orientation for all sections associated with that census point, given that it most closely represents the situation at the census point.

Road sources within ADMS-Roads are treated as line sources of variable width. To represent road widths as accurately as possible for all roads within the UK urban major roads coverage, the width has been estimated based on lane counts provided in the census point dataset. Road widths have been calculated assuming an average width of 4 metres per lane for urban single and dual carriageway A-roads and urban motorways. The 4-metre lane width assumption corresponds to those recommended by the Design Manual for Roads and Bridges (DMRB, 2005), where a lane width of

¹² <http://www.cerc.co.uk/environmental-software/ADMS-Roads-model.html>

¹³ A set of lines within Geographical Information System

3.65 metres is more typical and the difference in lane width takes into account the hardstrip for urban A-roads.

To provide confidence in the lane counts from the census points dataset and the lane widths calculated, these were verified for a subset of road links for the following cases:

- Where lane counts were not available
- Where only a single lane was indicated
- For road links with the highest traffic flows
- For road links where predictions indicated the highest concentrations in a zone
- For road links that were going to be included in the roadside calibration for the first time

Excluding those road links where only a single lane was indicated, for the assessed road links an average of 4 metres per lane was typical. Wider and more varied widths were observed for roads with only single lanes, but these are not characteristic of the complete dataset, typically being slip roads or small urban A-roads and carrying the least traffic (and represent less than 0.5% of the census points). All road sources are set up as line sources of length 2000 m. For road links that have not been assessed and a lane count has not been provided, the following default road widths have been assumed. The default characteristics are summarised in Table A8.1.

Table A8.1 - Default road source characteristics

Road type	Assumed number of lanes in each direction	Total width (m)	Length (m)
Single carriageway A-road	1	8	2000
Dual carriageway A-road	2	16	2000
Motorway	3	32	2000

Traffic speeds, emissions and traffic counts

ADMS-Roads uses traffic speeds and flows by vehicle category to estimate vehicle induced turbulence. The PCM-RKM uses traffic emissions for major road links in the UK provided directly by the NAEI and incorporates the vehicle induced turbulence as calculated by ADMS-Roads. Unitary emissions of 1 g/km/s are applied such that output concentrations profiles can be treated as kernels providing weightings for the pollutant specific road link emissions from the NAEI. The roadside increment concentration is calculated by multiplying concentrations modelled for unit emissions by the emissions rate for each road link. Traffic flows (annual average daily flows, AADFs) by census point have been aggregated into 2 vehicle categories i.e. light and heavy-duty vehicles for the calculation of vehicle induced turbulence.

Previously, traffic speed assumptions by vehicle category were applied following categories based upon UK area type and road type taking data from DfT congestion statistics to estimate the speeds. NAEI traffic speed assignments have been applied defined by region, land use and speed limit, see Section 4.3.6.

Emissions are assumed to be time varying, with temporal profiles varying by hour of the day, day of the week and having a seasonal monthly variation. The time varying emissions profiles for traffic are the same as those used for treating area source emissions from traffic in the PCM area source model (see Figure A5.1a and Figure A5.1b, Appendix 5 – Dispersion kernels for the area source model).¹⁴ The profiles were obtained from DfT traffic flow data for all traffic in Great Britain averaged over the period 2010-2014 (DfT, 2022a).

¹⁴ A 2021 specific monthly profile was used for 2021 in order to account for the timing of covid-19 lockdowns.

Meteorology

Hourly sequential meteorological data from the WRF model in the reference year has been used in the setup of the ADMS-Roads model runs (see Appendix 4 – WRF meteorology). Table A8.2 shows the other assumptions applied for details of the meteorological conditions at the roads, which are dependent on the area type and meteorological site. These are in common with the setup for the area source dispersion kernels in the PCM model (see Appendix 5 – Dispersion kernels for the area source model).

Table A8.2 - Summary of meteorological parameters applied by area type

Area types (from Table A7.2)	Types of location	Minimum Monin–Obukhov length (m)		Surface roughness (m)	
		Dispersion site	Meteorological site	Dispersion site	Meteorological site
1,2,4	Conurbation	25	Varies by predominant area type of WRF grid cell	1.0	Varies by WRF grid cell based on USGS Land Use
3,5,6,7,8	Smaller urban	20	Varies by predominant area type of WRF grid cell	0.5	Varies by WRF grid cell based on USGS Land Use
9,10	Rural	10	Varies by predominant area type of WRF grid cell	0.1	Varies by WRF grid cell based on USGS Land Use

Receptors locations

Model runs are set up with a road source for each major road link nearest to a census point. This road source represents the link at the road angle determined from the coordinates of its end nodes.

Concentrations are modelled for 49 receptors, with one at the road centre line of the road link, and 24 each side perpendicular to the road link. Close to the roadside the receptor spacing progressively increases to a maximum of 200 m from the roadside. A diagram illustrating the position of receptors and road source is given in Table A8.1.

Figure A8.1- Schematic diagram of road source (blue) and receptors (red)

Model outputs

Modelled concentrations can be derived from the ADMS-Roads model outputs for all receptor locations specified. In the PCM-RKM modelling the average concentration across each side of the road at a distance of 4 m from the kerb for all census points has been selected for comparison with the measured concentrations at roadside (traffic) stations for model calibration. The same output has also been used for the compliance assessment modelling for roadside (traffic) concentrations. To illustrate the variation in concentration modelled with distance from the road a normalised concentration profile is presented in Figure A8.2.

Figure A8.2 - Example normalised concentration profile

Model calibration

The PCM-RKM uses the PCM roadside increment approach for the prediction of the local contribution to total concentrations at the roadside. As such the annual mean concentration at roadside locations has been assumed to be made up of two parts: a background concentration (excluding local sources) and a roadside increment.

$$\text{Roadside concentration} = \text{background concentration} + \text{roadside increment}.$$

To calibrate the model, modelled concentrations are compared to measured roadside increment concentrations (i.e. measured roadside concentration minus modelled background concentration) at AURN roadside traffic stations. Figure 4.9 in Chapter 4 presents the calibration plot for NO_x for 2021 for the PCM-RKM.

Adjustment factors applied to road link emissions

The effect of street canyons has not been explicitly included in the PCM-RKM model. Instead the model calibration based on the comparison of measured and modelled roadside concentration increments implicitly includes some influence of street canyon effects, dependent on how much the local environment of the AURN road traffic stations used to calibrate the model can be characterised as street canyons. Street canyons are typically characterised in terms of aspect ratio, the ratio of the road width to the height of buildings lining the road. Vardoulakis et al. (2003) characterised avenue canyons as those with aspect ratios (AR) < 0.5, and deep canyons as those where AR = 2.

Motorways are expected to have a more open aspect than the urban streets where the AURN road traffic stations used to calibrate the model are situated. An adjustment factor has therefore been derived for motorways.

The AURN road traffic stations used to calibrate the model have been characterised in terms of AR from estimates of the average road widths (building façade to building façade) and average building heights determined by examining the roads within ArcMap, Google Earth and Google Streetview.

In development of the PCM-RKM, comparison of roadside modelling results to the previous PCM model output indicated significant increases in the modelled concentrations for roads with high traffic flows predicted by using ADMS-Roads. These increases are not thought realistic and indicate under-prediction of dispersion for the widest and highest flow roads since dispersion is likely to be most efficient on these roads. To address this, adjustment factors have been developed to apply to the road link emissions for motorways and A-roads where the traffic flow exceeds an annual average daily flow of 75,000.

The combined traffic flow and motorway adjustment factors as a function of traffic flow are presented in Figure A8.3.

Figure A8.3 - Combined adjustment factors applied to road link emissions for 2021

Model verification

Verification of the PCM-RKM for NO_x, NO₂, PM₁₀, PM_{2.5}, and benzene for the assessment year is discussed in the body of this report.

Appendix 9 – Selected acronyms

ADMS	Atmospheric Dispersion Modelling System
AEI	Average exposure indicator
AGANet	UK Acid Gases and Aerosols Monitoring Network (UK)
AOT40	Accumulated exposure index above a threshold concentration of 40 ppb
APU	Auxiliary power unit (aircraft)
AQD	Directive on ambient air quality and cleaner air for Europe (2008/50/EC), known as the 'Air Quality Directive'
AQDD4	The fourth Daughter Directive 2004/107/EC (AQDD4) under the Air Quality Framework Directive (1996/62/EC)
AQUILA	European Network of Air Quality Reference Laboratories
AQSR	Air Quality Standards Regulations 2010
As	Arsenic
AURN	Automatic urban and rural network (UK)
B(a)P	benzo(a)pyrene, a polycyclic aromatic hydrocarbon
BEIS	Department for Business, Energy & Industrial Strategy
Cd	Cadmium
CL	Critical level
CO	Carbon monoxide
COPERT	Software tool used to calculate air pollutant emissions from road transport
Defra	Department for Environment, Food & Rural Affairs
DQO	Data quality objective
ECO	Exposure concentration obligation
EEP	Energy and emissions projections
EMEP	European Monitoring and Evaluation Programme under the Convention on Long-range Transboundary Air Pollution
ERG	Environmental Research Group, Kings College London
ERT	Exposure Reduction Target
ETS	Emissions Trading Scheme
<i>f</i> -NO ₂	The fraction of NO _x emissions emitted as primary NO ₂ (by volume)
HDV	Heavy duty vehicles
IDW	Inverse Distance Weighting
IED	Industrial Emissions Directive (2010/75/EU)
IPR	Implementing Provisions on Reporting (Decision 2011/850/EU)
LAQN	London Air Quality Network
LEZ	Low Emission Zone
LMO	Monin Obukhov Length
LTO	Long term objective
LV	Limit value
MAAQ	Modelling Ambient Air Quality
NAEI	National Atmospheric Emissions Inventory (UK)

NAME	Numerical Atmospheric-dispersion Modelling Environment
NAMN	National Ammonia Monitoring Network (UK)
NERT	National Exposure Reduction Target
Ni	Nickel
NO	Nitrogen monoxide
NO ₂	Nitrogen dioxide
NO _x	Oxides of nitrogen
O ₃	Ozone
Pb	Lead
PCM	Pollution Climate Mapping
PCM-RKM	Pollution Climate Mapping Roads Kernel Model
PM	Particulate Matter
PM ₁₀	Particulate matter 10 micrometres or less in diameter
PM _{2.5}	Particulate matter 2.5 micrometres or less in diameter
SIA	Secondary inorganic aerosol
SNAP	Standardized Nomenclature for Air Pollutants (emissions inventory sector splits)
SO ₂	Sulphur dioxide
SOA	Secondary organic aerosol
TEOM	Tapered element oscillating microbalance
TEOM FDMS	Tapered element oscillating microbalance and Filter Dynamics Measurement System
TRACK	A receptor oriented, Lagrangian statistical air quality model
TV	Target value
UKEAP	United Kingdom Eutrophying & Acidifying Network
ULEZ	Ultra-Low Emission Zone
UUNN	UK Urban NO ₂ Network
VCM	Volatile correction model
WRF	Weather Research and Forecasting
